This chapter is in preparation for the book Ancient Supercontinents and the Paleogeography of the Earth

¹ 4.1 Abstract

Laurentia is the craton that forms the Precambrian core of North America and was a major continent throughout the majority of the Proterozoic. The paleogeographic position of Laurentia is key to the development of reconstructions of Proterozoic paleogeography including the Paleoproterozoic-Mesoproterozoic Nuna and Neoproterozoic Rodinia supercontinents. There is a rich record of Precambrian paleomagnetic poles from Laurentia, as well as an extensive and well-documented geologic history of tectonism. These geologic and paleomagnetic records are increasingly better constrained geochronologically and are both key to evaluating and developing paleogeographic models. These data from Laurentia provides strong-support for mobile lid plate tectonic processes operating continuously over the past 2.2 billion years.

¹¹ 4.2 Introduction and broad tectonic history

Laurentia refers to the craton that forms the Precambrian interior of North America and Greenland (Fig. 1). Laurentia comprises multiple Archean provinces that had unique histories prior to their amalgamation in the Paleoproterozoic, as well as tectonic zones of crustal growth that post-date this assembly (Hoffman, 1989; Whitmeyer and Karlstrom, 2007). Collision between the Superior province and the composite Slave+Rae+Hearne provinces that resulted in the Trans-Hudson orogeny represents a major event in the formation of Laurentia (Corrigan et al., 2009). Terminal collision recorded in the Trans-Hudson orogen is estimated to have been ca. 1.86 to 1.82 Ga based on constraints such as U-Pb dating of monazite grains and zircon rims (Skipton

20 et al., 2016; Weller and St-Onge, 2017, e.g.). A period of accretionary and collisional orogenesis is
21 recorded in the constituent provinces and terranes of Laurentia leading up to the terminal
22 collision of the Trans-Hudson orogeny. This overall story of rapid Paleoproterozoic amalgamation
23 of Laurentia's constituent Archean provinces, including the terminal Trans-Hudson orogeny, was
24 synthesized in the seminal *United Plates of America* paper of Hoffman (1988) and has been
25 refined in the time since – particularly with additional geochronological constraints. Of most
26 relevance here are the events that led to the suturing of more major Archean provinces: the
27 Thelon orogen associated with the collision between the Slave and Rae provinces ca. 2.0 to 1.9 Ga
28 (Hoffman, 1989); the Snowbird orogen associated with ca. 1.89 Ga collision between the Rae and
29 Hearne provinces and associated terranes (Berman et al., 2007); the Nagssugtoqidian orogen due
30 to the ca. 1.86 to 1.84 Ga collision between the Rae and North Atlantic provinces (St-Onge et al.,
31 2009); and the Torngat orogen resulting from the ca. 1.87 to 1.85 Ga collision of the Meta
32 Incognita province (grouped with the Rae province in older compilations) with the North Atlantic
33 province (St-Onge et al., 2009).

34 As for the suturing of the Wyoming province to Laurentia, many models posit that it was
35 conjoined with Hearne and associated provinces at the time of the Trans-Hudson orogeny (e.g.
36 St-Onge et al., 2009; Pehrsson et al., 2015) or was proximal to Hearne and Superior while still
37 undergoing continued translation up to ca. 1.80 Ga (Whitmeyer and Karlstrom, 2007). A
38 contrasting view has been proposed that the Wyoming province and Medicine Hat blocks
39 were not conjoined with the other Laurentia provinces until ca. 1.72 Ga (Kilian et al., 2016). This
40 interpretation is argued to be consistent with geochronological constraints on monazite and
41 metamorphic zircon indicating active collisional orogenesis associated with the Big Sky orogen on
42 the northern margin of the craton as late as ca. 1.75 to 1.72 Ga (Condit et al., 2015) and ca. 1.72
43 tectonomagmatic activity in the Black Hills region (Redden et al., 1990). However, the evidence
44 for earlier orogenesis ca. 1.78 to 1.75 in the Black Hills (Dahl et al., 1999; Hrncir et al., 2017), as
45 well as high-grade metamorphism as early as ca. 1.81 Ga in the Big Sky orogen (Condit et al.,
46 2015), may support the interpretation of Hrncir et al. (2017) that ca. 1.72 Ga activity is a minor
47 overprint on ca. 1.75 terminal suturing between Wyoming and Superior. Regardless, in both of
48 these interpretations, Wyoming is a later addition to Laurentia with final suturing post-dating ca.

49 1.82 Ga amalgamation of Archean provinces with the Trans-Hudson orogen further to the
50 northeast. Overall, the collision of these Archean microcontinents between ca. 1.9 and 1.8 Ga led
51 to rapid amalgamation of the majority of the Laurentia craton (Fig. 1).

52 Crustal growth also progressed in the Paleoproterozoic through accretionary orogenesis. This
53 accretion occurred within the Wopmay orogen through ca. 1.88 Ga arc-continent collision that led
54 to the accretion of the Hottah terrane (the Calderian orogeny) and the subsequent emplacement
55 of the Great Bear magmatic zone from ca. 1.88 to 1.84 Ga (Hildebrand et al., 2009). Coeval with
56 the Trans-Hudson orogeny was the peripheral Penokean orogeny during which both
57 microcontinent blocks (the Marshfield terrane) and arc terranes accreted on the southeastern
58 margin of the west Superior province ca. 1.86 to 1.82 (Schulz and Cannon, 2007). Firm evidence
59 of the end of the orogeny comes from the ca. 1.78 undeformed plutons of the post-Penokean East
60 Central Minnesota Batholith (Holm et al., 2005).

61 The collisions of provinces and terranes leading up to the Trans-Hudson orogeny mark the
62 initial phase of assembly of the supercontinent Nuna in the paleogeographic model framework of
63 Pehrsson et al. (2015). The Trans-Hudson orogeny itself is taken to be the terminal collision
64 associated with the closure of the Manikewan Ocean that had previously been a large oceanic
65 tract separating the Superior province from the composite Slave+Rae+Hearne+North Atlantic
66 provinces (often referred to as the Churchill domain or plate; e.g. Skipton et al., 2016; Weller and
67 St-Onge, 2017; Fig. 4). The paleogeographic mode of Pehrsson et al. (2015) posits that this
68 period of terminal collision not only resulted in the amalgamation of Laurentia, but was also
69 associated with the assembly of the supercontinent Nuna that is hypothesized to include other
70 major Paleoproterozoic cratons including Baltica, Siberia, Congo/São Francisco, West Africa, and
71 Amazonia.

72 Following the Trans-Hudson orogeny, the locus of orogenesis migrated to the exterior of
73 Laurentia. This change marks a shift in the predominant style of Laurentia's growth as
74 subsequent crustal growth occurred dominantly through accretion of juvenile crust along the
75 southern and eastern margin of the nucleus of Archean provinces (Whitmeyer and Karlstrom,
76 2007; Figs. 1 and 2). Determining the extent of these belts is complicated by poor exposure of
77 them in the midcontinent relative to the exposure of the Archean provinces throughout the

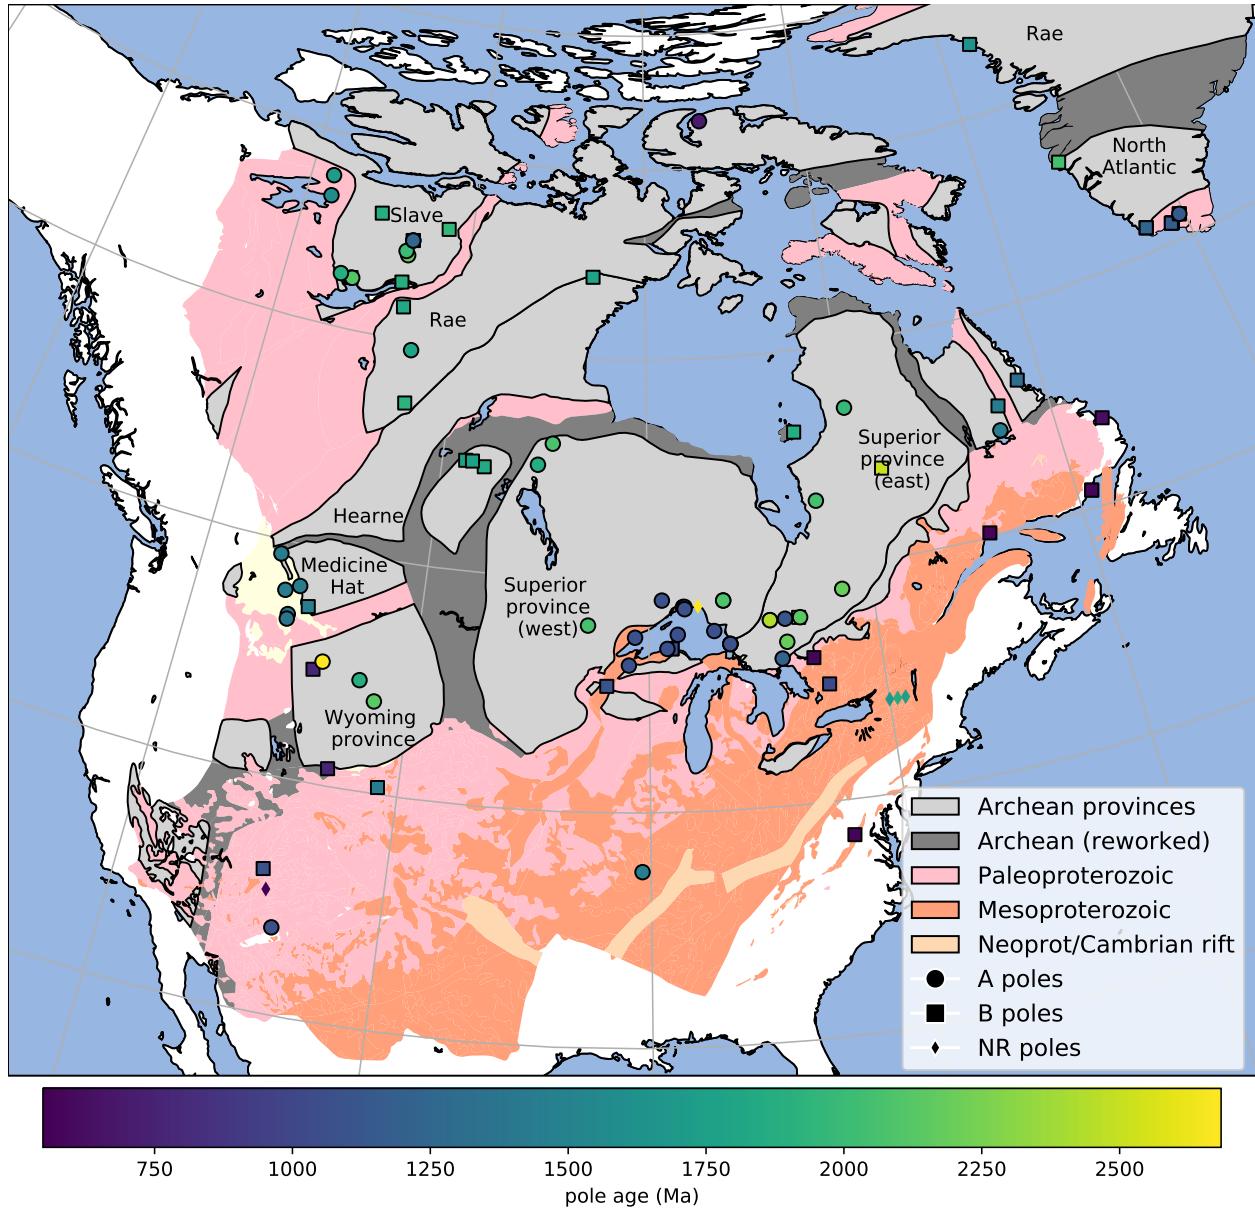

Figure 1. Simplified map of Laurentia showing the location of Archean provinces (labeled with text) and younger Paleoproterozoic and Mesoproterozoic crust (simplified from Whitmeyer and Karlstrom, 2007 with additions for Greenland based on St-Onge et al., 2009). The localities from which the compiled Precambrian paleomagnetic poles were developed are shown and colored by age. The circles (A rated poles) and squares (B rated poles) have been assessed by the Nordic workshop panel.

78 Canadian shield. Major growth of Laurentia following the amalgamation of these Archean
79 provinces occurred associated with the arc-continent collision of the ca. 1.71 to 1.68 Ga Yavapai
80 orogeny (Fig. 2). Yavapai orogenesis is interpreted to have resulted from the accretion of a series
81 of arc terranes that collided with each other and Laurentia (Karlstrom et al., 2001). Yavapai
82 accretion was followed by widespread emplacement of granitoid intrusions (Whitmeyer and
83 Karlstrom, 2007). These intrusions are hypothesized to have stabilized the juvenile accreted
84 terranes that subsequently remained part of Laurentia (Whitmeyer and Karlstrom, 2007).
85 Subsequent accretionary orogenesis of the ca. 1.65 to 1.60 Ga Mazatzal orogeny and associated
86 plutonism led to further crustal growth in the latest Paleoproterozoic (Karlstrom and Bowring,
87 1988). Laurentia's growth continued in the Mesoproterozoic along the southeast margin through
88 further juvenile terrane and arc accretion. An interval of major plutonism occurred ca. 1.48 to
89 1.35 Ga leading to the formation of A-type granitoids throughout both Mesoproterozoic and
90 Paleoproterozoic provinces extending from the southwest United States up to the Central Gneiss
91 Belt of Ontario to the northeast of Georgian Bay (Slagstad et al., 2009). This plutonism is likely
92 due to crustal melting within a back-arc region of ca. 1.50 to 1.43 Ga accretionary orogenesis
93 (Bickford et al., 2015). Geologic data from northern New Mexico have been interpreted to
94 indicate an interval of ca. 1.49 to 1.40 Ga orogenesis that has been named the Picuris orogeny
95 (Daniel et al., 2013). Younger magmatic activity ca. 1.37 Ga of the Southern Granite-Rhyolite
96 Province suggests a similar tectonic setting of accretionary orogenesis at that time (Bickford
97 et al., 2015). While an active margin interpretation with magmatism in a back-arc setting has
98 gained traction within the literature, the tectonic setting is often described as enigmatic given
99 earlier interpretations of an anorogenic setting (see references in Slagstad et al., 2009).

100 Accretionary orogenesis continued along the eastern margin of Laurentia with the
101 amalgamation and accretion of arcs associated with the ca. 1.25 to 1.22 Ga Elzevirian orogeny
102 (McLlland et al., 2013). The subsequent ca. 1.19 to 1.16 Ga Shawinigan orogeny is interpreted
103 to be due to the collision of terrane comprised of a previously rifted fragment of Laurentia and led
104 to obduction of the Pyrites Complex ophiolite (McLlland et al., 2010; Chiarenzelli et al., 2011).
105 The Shawinigan orogeny is followed by a period of tectonic quiescence on the eastern margin of
106 Laurentia until the collisional orogenesis of the Grenvillian orogeny (McLlland et al., 2010). An

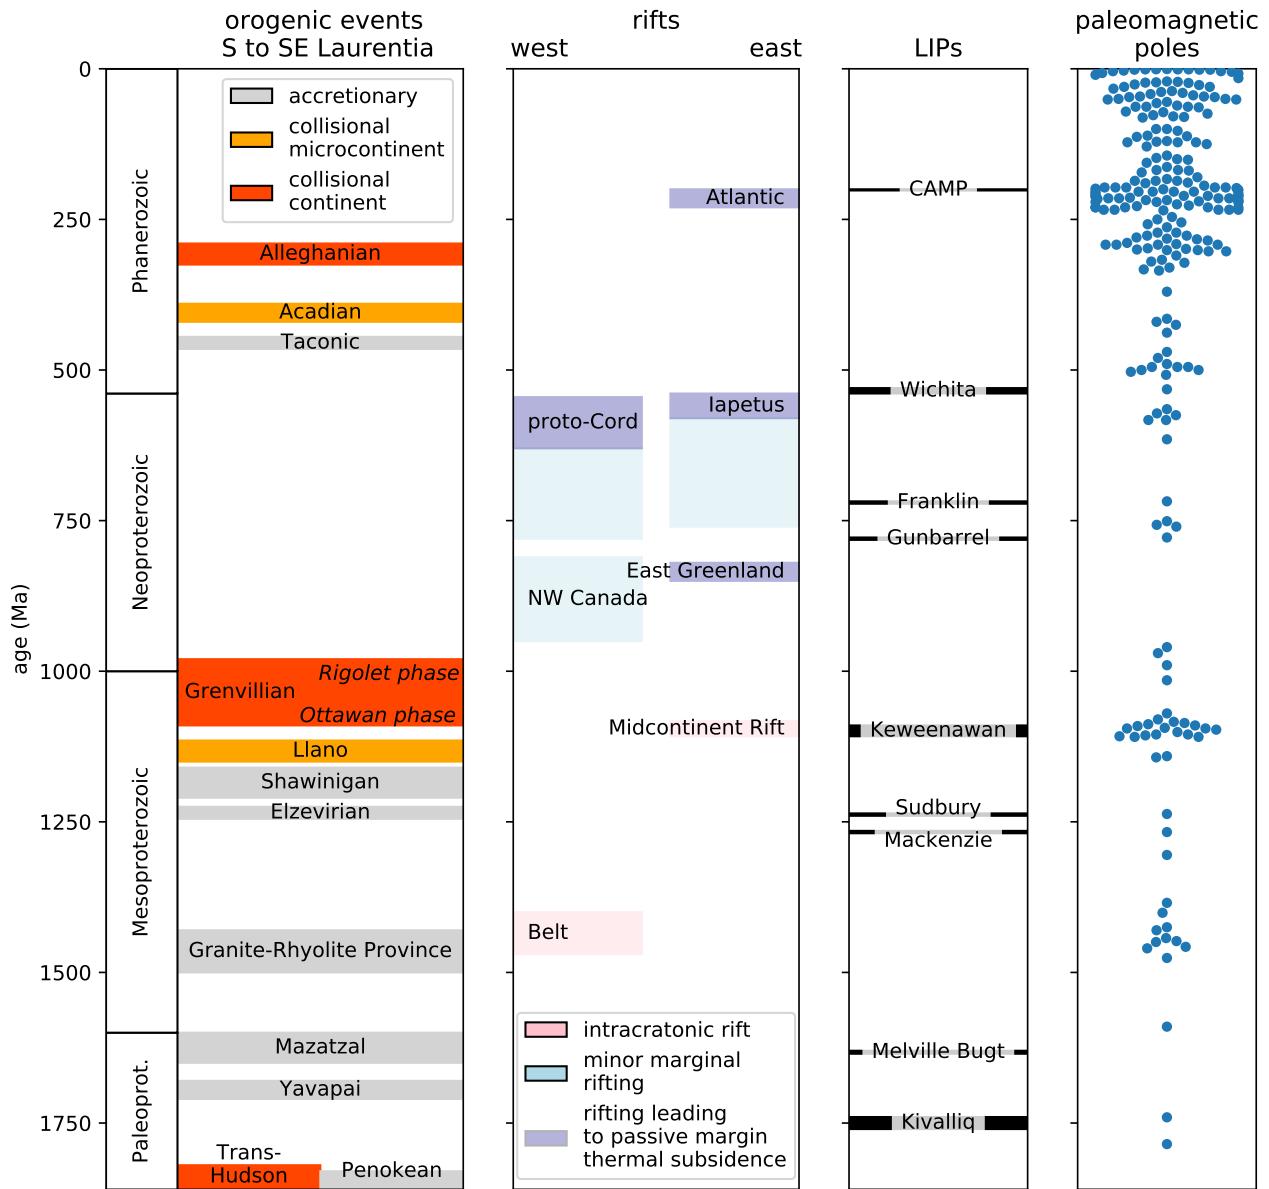

Figure 2. Simplified timeline of Laurentia's tectonic history over the past ~1.8 billion years. Brief summaries and references related to the orogenic and rifting episodes are given in the text. A timeline of large igneous provinces (LIPs) associated with typically brief and voluminous (or interpreted to be voluminous) volcanism is also shown. The interpreted age of paleomagnetic poles for Laurentia (not including separated terranes) compiled in this study for the Proterozoic and in Torsvik et al. (2012) for the Phanerozoic is shown. Abbreviations on the figure: CAMP (Central Atlantic Magmatic Province); proto-Cord (proto-Cordilleran).

107 exception to this quiescence during the interval between the Shawinigan and Grenvillian orogenies
108 is ca. 1.15 to 1.12 Ga orogenesis in the Llano uplift of the southern Laurentia margin (Mosher,
109 1998). Llano orogenesis is interpreted to have resulted from collision of continental lithosphere
110 along with an accreted arc (Mosher, 1998). This orogenesis is earlier and temporally distinct from
111 the Grenvillian orogeny, is only known from a limited spatial area, and is located in a region that
112 experienced further orogenesis during the Grenvillian orogeny (Grimes and Copeland, 2004).

113 Taken together, this context is suggestive of a microcontinent collision leading to Llano uplift
114 orogenesis prior to terminal Grenvillian continental collision. If this interpretation is correct, it is
115 similar to Paleozoic orogenesis along the margin where microcontinent collision resulted in the
116 Acadian orogeny prior to Alleghanian orogenesis during the Appalachian orogenic interval (2).

117 The Grenvillian orogeny was a protracted interval of continent-continent collision (ca. 1.09 to
118 0.98 Ga) leading to amphibolite to granulite facies metamorphism through the orogen (McLelland
119 et al., 2010). Evidence of large-scale continent-continent collision at the time of the Ottawan
120 Phase of the Grenvillian orogeny is recorded in Texas (Grimes and Copeland, 2004), up through
121 the Blue Ridge Appalachian inliers (Johnson et al., 2020), through Ontario and up to the
122 Labrador Sea (Rivers, 2008). The orogeny is interpreted to have resulted in the development of a
123 thick plateau associated with the Ottawan orogenic phase (ca. 1090 to 1030 Ma; Rivers, 2008).

124 Continued convergence during the Rigolet phase of the Grenvillian orogeny led to the
125 development of the Grenville Front tectonic zone and ended ca. 980 Ma (Hynes and Rivers, 2010).

126 In the latest Mesoproterozoic (ca. 1.11 to 1.08 Ga) prior to the Grenvillian orogeny, a major
127 intracontinental rift co-located with a large igneous province formed in Laurentia's interior
128 leading to extension within the Archean Superior province and adjacent Paleoproterozoic
129 provinces to the south (Cannon, 1992). This Midcontinent Rift led to the formation of a thick
130 succession of volcanics and mafic intrusions that are well-preserved in Laurentia's interior.
131 Midcontinent Rift development ceased as major collisional orogenesis of the Grenvillian orogeny
132 began (Swanson-Hysell et al., 2019).

133 There is significantly less preserved Mesoproterozoic crustal growth on the western margin of
134 Laurentia (Fig. 1), and the tectonic history through the Mesoproterozoic Era is not as well
135 elucidated as on the southern to eastern margin. The 15 to 20 km thick package of sedimentary

¹³⁶ rocks of the Belt-Purcell Supergroup is associated with a ca. 1.47 to 1.40 rift (Evans et al., 2000).
¹³⁷ While the rift is typically interpreted as being intracontinental (Lydon, 2004), the tectonic setting
¹³⁸ in which it formed is debated. Hoffman (1989) proposed that it may be a remnant back-arc basin
¹³⁹ trapped within a continent, while others envision it as being associated with continental rifting
¹⁴⁰ along the margin associated with separation of a conjugate continent (Jones et al., 2015). This
¹⁴¹ region is interpreted to have been subsequently deformed during a ca. 1.36 to 1.33 Ga event
¹⁴² known as the East Kootenay orogeny (McMechan and Price, 1982; Nesheim et al., 2012;
¹⁴³ McFarlane, 2015).

¹⁴⁴ This late Paleoproterozoic and Mesoproterozoic tectonic history provides significant
¹⁴⁵ constraints on paleogeographic reconstructions. In particular, the long-lived history of
¹⁴⁶ accretionary orogenesis along the southeast (present-day coordinates) of Laurentia from the
¹⁴⁷ initiation of the Yavapai orogeny (ca. 1.71 Ga) to the end of the Shawinigan orogeny (ca. 1.16
¹⁴⁸ Ga) requires a long-lived open margin without a major conjugate continent until the time of
¹⁴⁹ terminal Grenvillian orogeny collision (Karlstrom et al., 2001). This constraint is incorporated
¹⁵⁰ into models such as that of Zhang et al. (2012) and Pehrsson et al. (2015) which maintain a
¹⁵¹ long-lived convergent margin throughout the Mesoproterozoic, but in some reconstructions other
¹⁵² continental blocks are reconstructed into positions that are seemingly incompatible with this
¹⁵³ record of accretionary orogenesis (e.g. Amazonia in Elming et al., 2009). The high-grade
¹⁵⁴ metamorphism associated with the Ottawan phase of the Grenvillian orogeny itself strongly
¹⁵⁵ suggests a collision between Laurentia and (an)other continent(s) ca. 1080 Ma – the geological
¹⁵⁶ observation of which first led to the formulation of the hypothesis of the supercontinent Rodinia
¹⁵⁷ (Hoffman, 1991). This extensive and major collisional orogenic history recorded in Laurentia, and
¹⁵⁸ also present on other Proterozoic continents, at this time remains a strong piece of evidence that
¹⁵⁹ a supercontinent or (proto)supercontinent formed at the 1.0 Ga Mesoproterozoic to
¹⁶⁰ Neoproterozoic transition. Note that while the term Grenville orogeny or Grenville belt is used
¹⁶¹ rather loosely throughout much of the literature to refer to any late Mesoproterozoic orogenic
¹⁶² belt, the timeline of orogenesis on the Laurentia margin has more nuanced constraints than this
¹⁶³ usage. These constraints can be comparatively assessed when evaluating potential conjugate
¹⁶⁴ continents to Laurentia associated with the orogen (Fig. 2).

165 The subsequent Neoproterozoic tectonic history of Laurentia is dominantly a record of rifting
166 (Fig. 2). Along the western margin of Laurentia, rifting occurred ca. 780 to 720 Ma leading to
167 deposition in basins from the Death Valley region of SW Laurentia to the Mackenzie Mountains
168 of NW Laurentia (Macdonald et al., 2013; Dehler et al., 2017; Rooney et al., 2017). However, this
169 extensional basin development predates the rifting that led to well-documented passive margin
170 thermal subsidence closer to the ca. 539 Ma Neoproterozoic-Phanerozoic boundary (Bond et al.,
171 1984; Levy and Christie-Blick, 1991). The emplacement of the ca. 780 Ma Gunbarrel large
172 igneous province along this margin and the subsequent extension recorded in the basins is
173 commonly interpreted to be associated with the break-up of Laurentia and a conjugate continent
174 to the western margin (often interpreted to be Australia). If this interpretation is correct, it is
175 unclear why there would be minimal thermal subsidence until the Ediacaran (post 635 Ma as in
176 Levy and Christie-Blick, 1991 and Witkosky and Wernicke, 2018). The geological evidence
177 therefore supports prolonged active tectonism along the western margin of Laurentia (a portion of
178 which could be strike-slip and transtensional; Smith et al., 2015), but suggests that there was
179 significant lithospheric thinning associated with rifting later than the timing of rifting typically
180 implemented in models of Rodinia break-up. The record of Neoproterozoic basin development
181 lead Yonkee et al. (2014) to propose that the early ca. 780 Ma rifting was intracratonic and that
182 while it may have led to some associated thermal subsidence that there was a second interval of
183 rifting and thermal subsidence associated with Australia rifting away in the Ediacaran (later than
184 in most models). Another possibility, along the lines of that proposed in Ross (1991), is that ca.
185 780 Ma extensional tectonism is an inboard record of rifting and passive margin development that
186 occurred further outboard. In this model, subsequent continent rifting that drove lithospheric
187 thinning, perhaps associated with the departure of a microcontinent fragment rather than an
188 already departed major conjugate continent, would be the cause of Ediacaran to Cambrian
189 thermal subsidence.

190 In northwest Laurentia from the Ogilvie Mountains of Yukon to Victoria Island, the
191 sedimentary rock record is distinct from further south as it also records earlier Neoproterozoic
192 basin development during the Tonian Period in addition to Cryogenian basin development
193 (Macdonald et al., 2012). Tectonic extension is recorded in units of the lower Fifteenmile Group

194 with maximum depositional ages of ca. 1050 Ma with ongoing basin development ca. 812 Ma (age
195 constraint from a U-Pb zircon date on a tuff within the upper Fifteenmile Group; Macdonald
196 et al., 2010) potentially through thermal subsidence (Macdonald et al., 2012). Earlier basin
197 development in the region recorded by the Mesoproterozoic/Neoproterozoic Pinguicula Group
198 could provide valuable insight on tectonic history as it has been interpreted to have been
199 deposited in an extensional basin (Medig et al., 2016), however it is poorly constrained in terms of
200 age – older than the Fifteenmile Group and younger than the ca. 1382 Ma Hart River sills (which
201 themselves have been interpreted to be emplaced in conjunction with rifting; Verbaas et al., 2018).

202 Another margin that experienced rifting and associated passive margin thermal subsidence
203 earlier in the Neoproterozoic is the northeast Greenland margin (Fig. 2). Available
204 geochronological constraints and thermal subsidence modeling indicate ca. 850 to 820 Ma rifting
205 followed by thermal subsidence of a stable platform (Maloof et al., 2006; Halverson et al., 2018).
206 These data suggest that conjugate continental lithosphere had rifted away from northeast
207 Greenland by ca. 820 Ma.

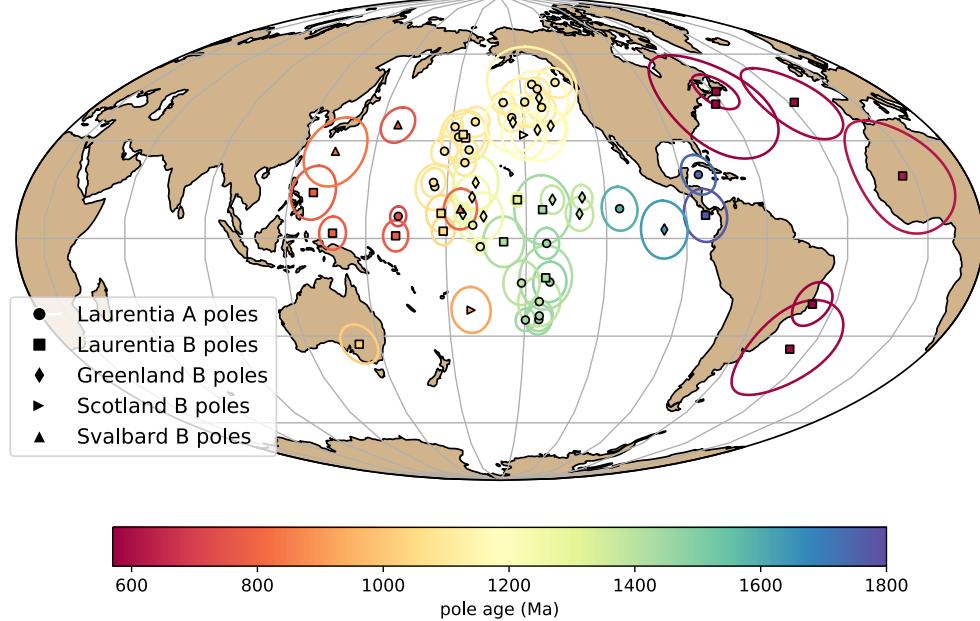

208 Extensive rifting followed by thermal subsidence occurred along the southeast to east Laurentia
209 margin in the time leading up to the Neoproterozoic-Phanerozoic boundary and is interpreted to
210 be associated with the opening of the Iapetus ocean. A record of this rifting is preserved as rift
211 basins that were part of failed arms (Rome trough, Reelfoot rift and Oklahoma aulacogen; Fig. 1)
212 as well as prolonged Cambrian to Ordovician passive margin thermal subsidence along the margin
213 (Bond et al., 1984; Whitmeyer and Karlstrom, 2007). The age of igneous intrusions that have
214 been interpreted to be rift-related play a significant role in interpretations of this history such as
215 in the rift development model of Burton and Southworth (2010). In this model,
216 spatially-restricted rifting occurs ca. 760 to 680 Ma in the region of modern-day North Carolina
217 and Virginia. Rifting ca. 620 to 580 Ma initiates in the region from modern-day New York to
218 Newfoundland and by ca. 580 to 550 Ma rifting extends along the length of Laurentia's eastern
219 margin. The last phase of this rifting has been interpreted to be associated with the separation of
220 the Argentine pre-Cordillera Cuyania terrane (Dickerson and Keller, 1998). As with other rifts, it
221 is difficult to distinguish the separation of a cratonic fragment as a microcontinent from the
222 rifting and departure of a major craton, as the record that lingers on the craton is similar.

223 Recognizing this ambiguity, Robert et al. (2020) propose that rather than being associated with
224 spatially-restricted or failed rifting that ca. 700 Ma extension is associated with breakup and
225 separation of Laurentia and its conjugate continent (that they interpret to be Amazonia). This
226 rifting would have led to the formation of the Paleo-Iapetus Ocean (an analogue with the
227 Paleo-Thethys). Subsequent to this rifting of the major continental blocks, smaller terranes of
228 lithosphere rift off the east Laurentia ca. 600 Ma leading to the formation of the Neo-Iapetus
229 Ocean and the record of passive margin development on Laurentia (Robert et al., 2020).

230 The eastern margin of Laurentia then went through the multiple phases of Appalachian
231 orogenesis. As is visualized in Figure 2, there are parallels between the Grenville orogenic interval
232 and the Appalachian orogenic interval in that there was a period of arc-continent collision
233 (Elzevirian orogeny in the Grenville interval; Taconic orogeny in the Appalachian interval)
234 followed by microcontinent accretion (Shawinigan/Llano orogenies in the Grenville interval;
235 Acadian orogeny in the Appalachian interval) that culminated in large-scale continent-continent
236 collision (Grenvillian orogeny in the Grenville interval; Alleghanian orogeny in the Appalachian
237 interval). These similarities are the consequence of an active margin facing an ocean basin that
238 was progressively consumed until continent-continent collision. In the case of the Grenville
239 interval, this terminal collision is interpreted to be associated with the assembly of the
240 supercontinent Rodinia, and in the Appalachian interval it is interpreted to be associated with
241 the assembly of the supercontinent Pangea.

242 Even without considering other continents on Earth, the geological record of Paleoproterozoic
243 collisional of Archean provinces combined with accretionary orogenesis at that time and through
244 the rest of the Paleoproterozoic and Mesoproterozoic Eras provides strong evidence for mobile
245 plate tectonics driving Laurentia's evolution throughout the past 2 billion years. This tectonic
246 history inferred from geological data can be enhanced through integration with the paleomagnetic
247 record.

Poles for Laurentia (post-Paleoproterozoic amalgamation; with terranes)

Poles for Laurentia (pre-Paleoproterozoic amalgamation)

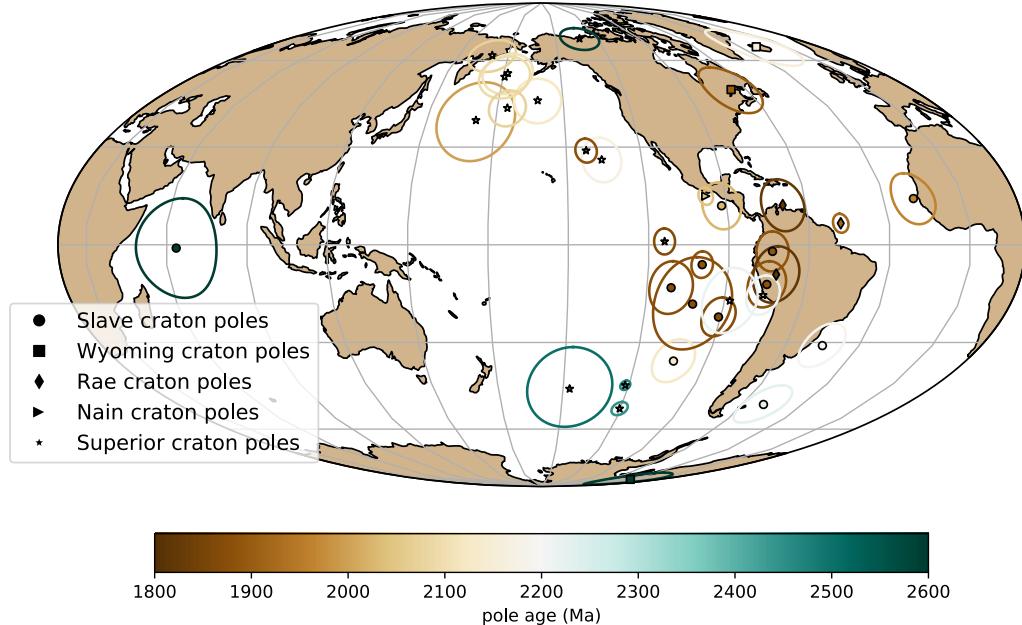

Figure 3. Top panel: Paleomagnetic poles from 1800 to 560 Ma for Laurentia (including Greenland, Scotland and Svalbard). Bottom panel: Paleomagnetic data for Archean Provinces prior to the amalgamation of Laurentia.

²⁴⁸ **4.3 Paleomagnetic pole compilation**

²⁴⁹ In this chapter, I focus on the compilation of paleomagnetic poles developed through the Nordic
²⁵⁰ Paleomagnetism Workshops with some additions and modifications (Fig. 3 and Table 2). The
²⁵¹ Nordic Paleomagnetism Workshops have taken the approach of using expert panels to assess
²⁵² paleomagnetic poles and assign them grades meant to convey the confidence that the community
²⁵³ has in these results (Evans et al., this volume). While many factors associated with
²⁵⁴ paleomagnetic poles can be assessed quantitatively through Fisher statistics and the precision of
²⁵⁵ geochronological constraints, other aspects such as the degree to which available field tests
²⁵⁶ constrain the magnetization to be primary require expert assessment. The categorizations used by
²⁵⁷ the expert panel are ‘A’ and ‘B’ with the last panel meeting occurring in Fall 2017 in Leirubakki,
²⁵⁸ Iceland. The ‘A’ rating refers to poles that are judged to be of such high quality that they
²⁵⁹ provide essential constraints that should be satisfied in paleogeographic reconstructions. The ‘B’
²⁶⁰ rating is associated with poles that are judged to likely provide a high-quality constraint, but
²⁶¹ have some deficiency such as remaining ambiguity in the demonstration of primary remanence or
²⁶² the quality/precision of available geochronologic constraints. Additional poles that were not given
²⁶³ an ‘A’ or ‘B’ classification at the Nordic Workshops are referred to as not-rated (‘NR’). These
²⁶⁴ additional poles are taken from the Paleomagia database (Veikkolainen et al., 2014). Many of
²⁶⁵ these poles in the Paleomagia database are quite valuable for reconstruction and should not be
²⁶⁶ dismissed from being considered in paleogeographic reconstructions. However, there are
²⁶⁷ ambiguities associated with many of the poles not given Nordic ‘A’ or ‘B’ ratings in terms of how
²⁶⁸ well the nature of the remanence is constrained, including its age. For example, there are rich
²⁶⁹ data associated with intrusive and metamorphic lithologies of the Grenville Province that are the
²⁷⁰ available paleomagnetic constraints for Laurentia at the Mesoproterozoic-Neoproterozoic
²⁷¹ boundary. However, the ages of the remanence associated with these poles is complicated by the
²⁷² reality that the magnetization was acquired during exhumation and such cooling ages are more
²⁷³ difficult to robustly constrain than the ages of remanence associated with dated eruptive units or
²⁷⁴ shallow-level intrusions. As a result, the vast majority of Grenville Province poles are not given
²⁷⁵ an ‘A’ or ‘B’ rating with the exception of the ‘B’ rated pole from the ca. 1015 Ma Haliburton
²⁷⁶ intrusions. However, while any one of these Grenville poles could be interpreted to suffer from

277 large temporal uncertainty, the overall preponderance of poles in a similar location at the time
278 suggests that they need to be taken seriously within paleogeographic reconstructions of Laurentia
279 (although an alternative view of an allochthonous origin put forward by Halls et al. (2015) is
280 discussed below). In this compilation, the poles of Brown and McEnroe (2012) from the
281 Adirondack highlands are used wherein the magnetic mineralogy and associated relative ages of
282 remanence are relatively well-constrained (Table 2). An additional not-rated pole included in the
283 present compilation is the new pole for the ca. 1144 Ma Ontario lamprophyre dikes (Piispa et al.,
284 2018) that strengthens the position of Laurentia at the time and coincides with the position of the
285 poles from the ca. 1140 Ma Abitibi dikes (Ernst and Buchan, 1993). This pole will likely receive
286 an ‘A’ rating when assessed at the next Nordic paleomagnetism workshop. Poles from the
287 Neoproterozoic Chuar Group of southerwest Laurentia as presented in Eyster et al. (2019) are
288 also included.

289 **4.4 Differential motion before Laurentia amalgamation**

290 Prior to the termination of the Trans-Hudson orogeny (before 1.8 Ga), paleomagnetic poles need
291 to be considered with respect to the individual Archean provinces. For the Superior province, an
292 additional complexity is that paleomagnetic poles from Siderian to Rhyacian Period (2.50 to 2.05
293 Ga) dike swarms, as well as deflection of dike trends, support an interpretation that there was
294 substantial Paleoproterozoic rotation of the western Superior province relative to the eastern
295 Superior province across the Kapuskasing Structural Zone (Bates and Halls, 1991; Evans and
296 Halls, 2010). This interpretation is consistent with the hypothesis of Hoffman (1988) that the
297 Kapuskasing Structural Zone represents major intracratonic uplift related to the Trans-Hudson
298 orogeny. Evans and Halls (2010) propose an Euler rotation of (51°N, 85°W, -14°CCW) to
299 reconstruct western Superior relative to eastern Superior and interpret that the rotation occurred
300 in the time interval of 2.07 to 1.87 Ga. I follow this interpretation and group the poles into
301 Superior (West) and Superior (East). Uncertainty remains with respect to whether the ca. 1.88
302 Ga Molson dikes pole pre-dates or post-dates this rotation (Evans and Halls, 2010) and thus for
303 the time being should be considered solely in the western Superior province reference frame.

304 There are poles in the compilation for the Slave, Wyoming, Rae, Superior and North Atlantic

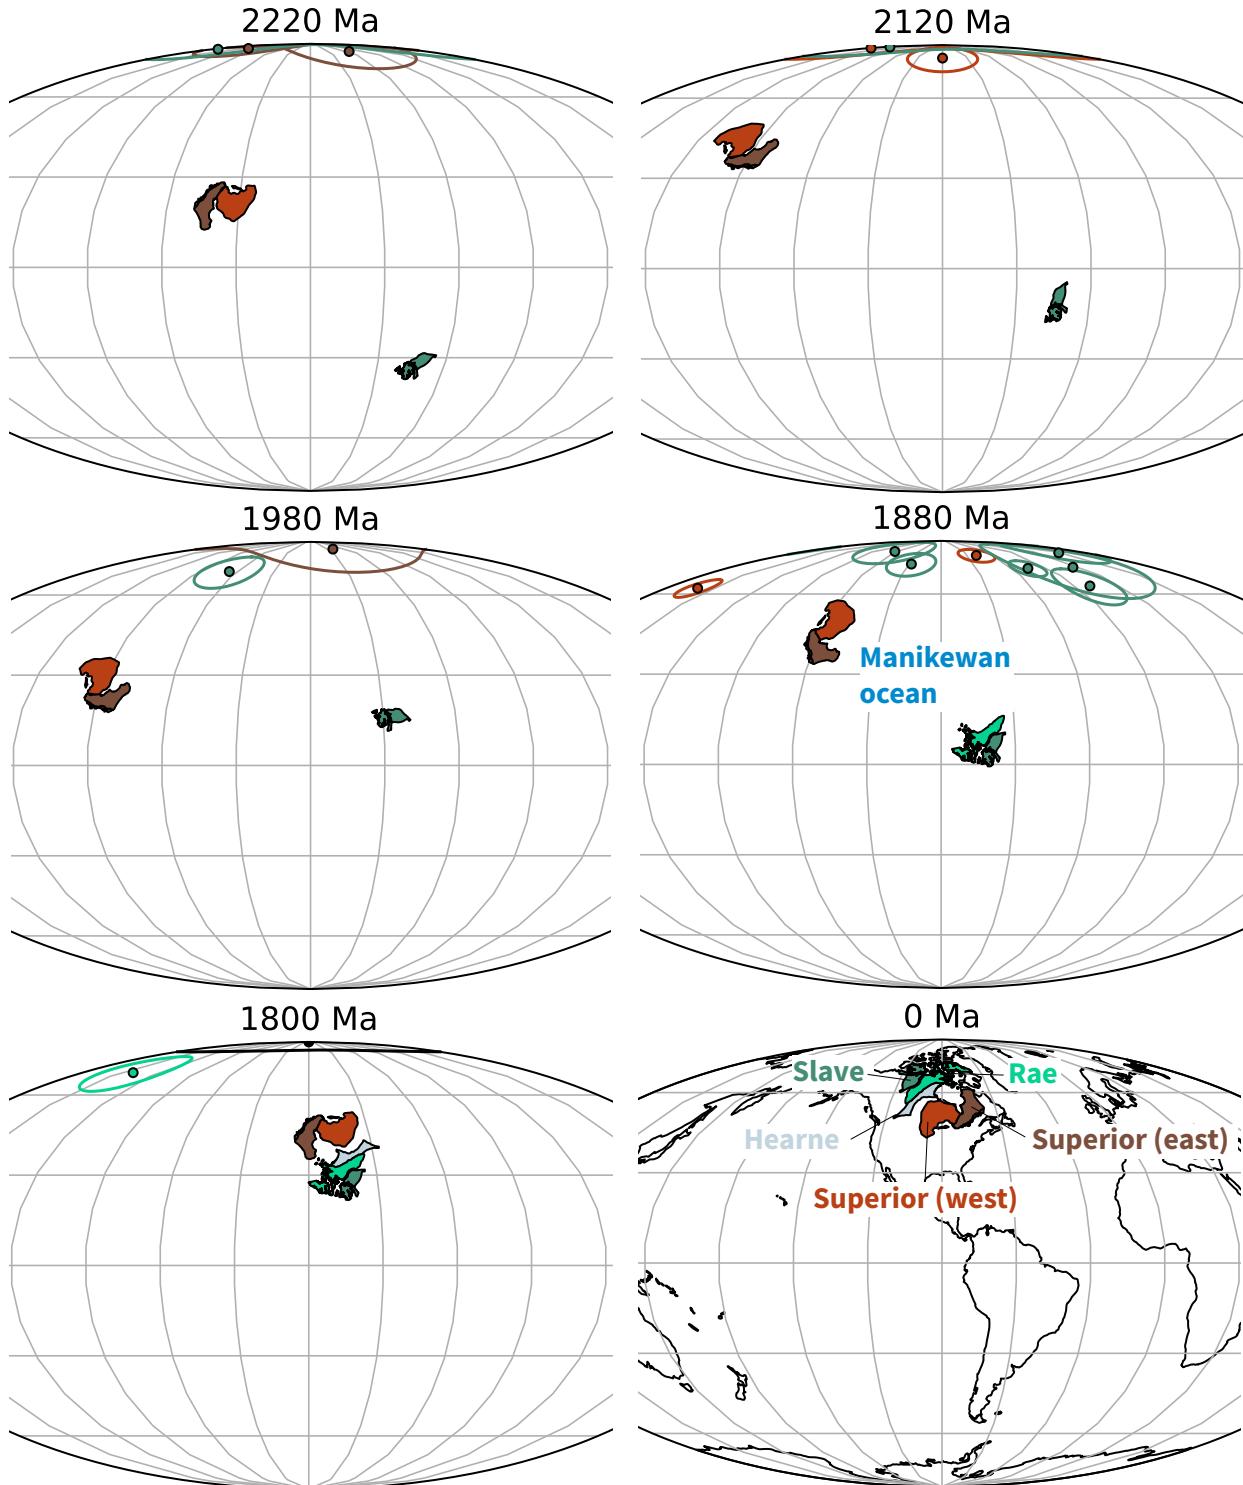

Figure 4. Paleogeographic reconstructions developed using poles from the Superior, Slave and Rae provinces. The polarity options that are chosen for the provinces are those that minimize total apparent polar wander path length. This model reconstructs a wide Manikewan ocean that underwent orthogonal closure rather than an alternative possibility of narrower Manikewan with a pivot-like closure. Paleomagnetic poles are shown colored to match their respective province with these provinces shown in present-day coordinates and labeled in the 0 Ma panel. Poles with ages that are within 25 million years of the given time slice are shown. The relatively well-resolved pole paths from the Superior and Slave provinces (Fig. 3) that are utilized for these reconstructions provide strong support for differential plate tectonic motion between 2220 and 1850 Ma.

provinces prior to Laurentia amalgamation (Fig. 3 and Table 2). Overall, these data provide an opportunity to re-evaluate the paleomagnetic evidence for relative motions between Archean provinces prior to Laurentia assembly. A lingering question raised in Hoffman (1988) is to what extent the Archean provinces each had independent drift histories with significant separation or shared histories before experiencing fragmentation and reamalgamation. The strongest analysis in this regard comes from comparisons between paleomagnetic poles between the Superior and Slave provinces (Buchan et al., 2009; Mitchell et al., 2014; Buchan et al., 2016). High-quality paleomagnetic poles from these two provinces provide strong support for differential motion between the Superior and Slave provinces between 2.2 and 1.8 Ga with the two provinces not being in their modern-day relative orientation to one another and having distinct pole paths as constrained by five time slices of nearly coeval poles from 2.23 and 1.89 Ga (Fig. 4; Buchan et al., 2016). These data provide paleomagnetic support for the Superior and Slave provinces having independent histories of differential motion. The data also support the hypothesis that the Trans-Hudson orogeny is the result of terminal collision associated with the closure of an ocean basin between the Superior province and the Hearne+Rae+Slave provinces. Reconstructions developed for this chapter of the Superior and Slave provinces using these poles are shown in Figure 4 and illustrate the difference in implied orientation and paleolatitude that results from these well-constrained poles.

4.5 Paleogeography of an assembled Laurentia

Following the amalgamation of the Archean provinces in Laurentia ca. 1.8 Ga, poles from each part of Laurentia can be considered to reflect the position of the entire composite craton. It is worth considering the possibility that poles from zones of Paleoproterozoic and Mesoproterozoic accretion could be allochthonous to the craton. Halls (2015) argued that this was the case for late Mesoproterozoic and early Neoproterozoic poles from east of the Grenvillian allochthon boundary fault. However, the majority of researchers have considered these poles to post-date major differential motion and be associated with cooling during collapse of a thick orogenic plateau developed during continent-continent collision (e.g. Brown and McEnroe, 2012). Poles with a B-rating are also included in the compilation that come from Greenland, Svalbard and Scotland.

333 These terranes were once part of contiguous Laurentia, but have subsequently rifted away. These
334 poles need to be rotated into the Laurentia reference frame prior to use for tectonic
335 reconstruction, and I apply the rotations shown in Table 1. The Euler pole and rotation is quite
336 well-constrained for Greenland as it is associated with recent opening of Baffin Bay and the
337 Labrador Sea (for which the rotation of Roest and Srivastava, 1989 is used). The reconstruction
338 of Scotland is associated with the opening of the Atlantic (for which the rotation employed by
339 Torsvik and Cocks, 2017 is used) which is well-constrained, but has more uncertainty associated
340 with the Euler pole than that for Greenland. The reconstruction of Svalbard is more challenging
341 given a multi-stage tectonic history involving both translation within the Caledonides and
342 subsequent rifting. The preferred Euler pole parameters of Maloof et al. (2006) are used here for
343 this reconstruction. This Euler rotation is designed, in particular, to honor the high degree of
344 similarity between Tonian sediments in East Greenland (Hoffman et al., 2012) and those of East
345 Svalbard (Maloof et al., 2006) and to reconstruct East Svalbard to be aligned with these
346 correlative sedimentary rocks.

347 Through the Proterozoic, there are intervals where there are abundant paleomagnetic poles
348 that constrain Laurentia's position and intervals when the record is sparse (shown colored by age
349 in Fig. 3). To further visualize the temporal coverage of the poles and to summarize the motion,
350 implied paleolatitudes for an interior point on Laurentia are shown in Figure 5. The ages of the
351 utilized paleomagnetic poles are also shown in comparison to the simplified summary of tectonic
352 events in Figure 2. Both collisional and extensional tectonism can result in the formation of
353 lithologies that can be used to develop paleomagnetic poles either as a result of basin formation,
354 magmatism or both. In addition, intraplate magmatism resulting from plume-related
355 large-igneous provinces can lead to paleomagnetic poles in periods that are otherwise
356 characterized by tectonic quiescence (e.g. the ca. 1267 Ma Mackenzie LIP; Fig. 2).
357 Intracontinental rifts have led to the highest density of poles both in the case of the ca. 1.4 Ga
358 Belt Supergroup and the ca. 1.1 Ga Midcontinent Rift (Fig. 2). The quality and resolution of the
359 record from the Midcontinent Rift is aided by the voluminous magmatism that occurred in
360 conjunction with basin formation that enables the development of a well-calibrated apparent
361 polar wander path (Swanson-Hysell et al., 2019). The late Tonian Period also has a number of

362 poles including the Gunbarrel LIP (ca. 780 Ma) and Franklin LIP (ca. 720 Ma), as well as
363 similarly-aged sedimentary rocks from western Laurentia basins (Eyster et al., 2019). Overall,
364 there is internal consistency among the paleomagnetic poles within intervals for which there is
365 high-resolution coverage. These data result in progressive paths such as ascending up to the
366 Logan Loop, down the Keweenawan Track (Swanson-Hysell et al., 2019) to the Grenville Loop
367 prior to a temporal gap before the late Tonian (ca. 775 to 720 Ma) path (Eyster et al., 2019).

368 Data from other terranes add resolution to the record. In particular, data from Greenland add
369 12 poles between 1385 and 1160 Ma when there are only four poles from mainland Laurentia.
370 Given that the rotation between Greenland and mainland Laurentia is well-constrained (Table 1),
371 once rotated these poles can be used for reconstruction of the entire continent. The reliability of
372 this approach gains credence through the good agreement between the ca. 1633 Ma Melville Bugt
373 diabase dikes pole from Greenland (Halls et al., 2011) and the ca. 1590 Ma Western Channel
374 diabase pole of mainland Laurentia (Irving and Park, 1972). Similarly, there is good agreement
375 between the ca. 1267 Ma Mackenzie dikes pole of Laurentia (Buchan et al., 2000) and coeval
376 poles from Greenland such as the ca. 1275 Ma North Qoroq intrusives (Piper, 1992) and Kungnat
377 Ring dike (Piper, 1977). Furthermore, the Greenland poles with ages that fall between the ca.
378 1237 Ma Sudbury dikes and ca. 1144 Ma lamprophyre dikes pole of mainland Laurentia are
379 consistent with constraints on either side from the mainland while filling in the ascending limb of
380 the path leading up to the apex of 1140 to 1108 Ma poles known as the Logan Loop.

381 An exception to this overall agreement between poles from Greenland and mainland Laurentia
382 occurs ca. 1382 Ma. There are poles of this age from Greenland associated with the Zig-Zag Dal
383 basalts and related intrusions (Marcussen and Abrahamsen, 1983; Abrahamsen and Van Der Voo,
384 1987). However, these poles are in a distinct location from poles of similar age associated with the
385 Belt Supergroup (e.g. the McNamara Formation and Pilcher/Garnet Range and Libby
386 Formations; Elston et al., 2002). Additionally, the older Belt Supergroup poles form a more
387 southerly population than time-equivalent poles from elsewhere in Laurentia such as the Mistastin
388 Pluton. There are potential complications associated with the Belt Supergroup being exposed
389 within thrust sheets with significant Cenozoic Mesozoic and Cenozoic deformation. However,
390 vertical axis rotations of the Belt region are not able to bring the Belt poles into agreement with

391 those from Laurentia or Greenland nor is translation away from the craton. Another potential
392 complication is that the remanence used for the development of the Belt Supergroup resides in
393 hematite. As a result, there is the potential for inclination-flattening within the sedimentary rocks
394 from which poles are developed. However, applying a moderate inclination factor of $f = 0.6$ also
395 does not bring the poles into congruence with the Zig-Zag basalts. There is the potential that the
396 hematite could be the result of post-depositional oxidation (the remanence of the lavas pole is
397 also held by hematite), however the overall coherency of the pole directions and the presence of
398 reversals has been taken as evidence that the remanence is primary (Elston et al., 2002). At
399 present, it is unclear which poles are a better representation of Laurentia's position ca. 1400 Ma.

400 Another challenging portion of the Laurentia paleomagnetic record is that for the Ediacaran
401 Period where there is little consistency between poles of similar age (Figs. 3 and 5). As a result,
402 there are poles that imply both low-latitude and high-latitude positions of Laurentia between 615
403 and 565 Ma. One explanation for these variable pole positions is that they are the result of
404 large-scale oscillatory true polar wander in the Ediacaran where rapid rotation of the entire
405 silicate Earth influenced poles in Baltica and West Africa as well (McCausland et al., 2007; Robert
406 et al., 2017). Another possibility is that the lack of congruency between poles in this point in the
407 record is due to a particularly weak and non-dipolar geomagnetic field (Abrajevitch and Van der
408 Voo, 2010; Halls et al., 2015; Bono et al., 2019). Regardless of mechanism, the Ediacaran data
409 stand out as anomalous relative to the coherency of the rest of the poles in the composite (Fig. 5).

410 Synthesizing the compilation of paleomagnetic poles for Laurentia into a composite path over
411 the past 1.8 billion years presents a challenge given the highly variable temporal coverage. The
412 method typically applied in the Phanerozoic is to develop synthesized pole paths either through
413 fitting spherical splines through the data or calculating binned running means where the Fisher
414 mean of poles within a given interval are calculated (Torsvik et al., 2012). Applying such an
415 approach can reduce the influence of spurious poles. Such synthesis is particularly important in
416 regions of high data density where seeking to satisfy every mean pole position would result in
417 jerky motion.

418 A synthesized pole path for Laurentia is developed here and used to develop a paleogeographic
419 reconstruction of Laurentia constrained by the compilation of paleomagnetic poles. The

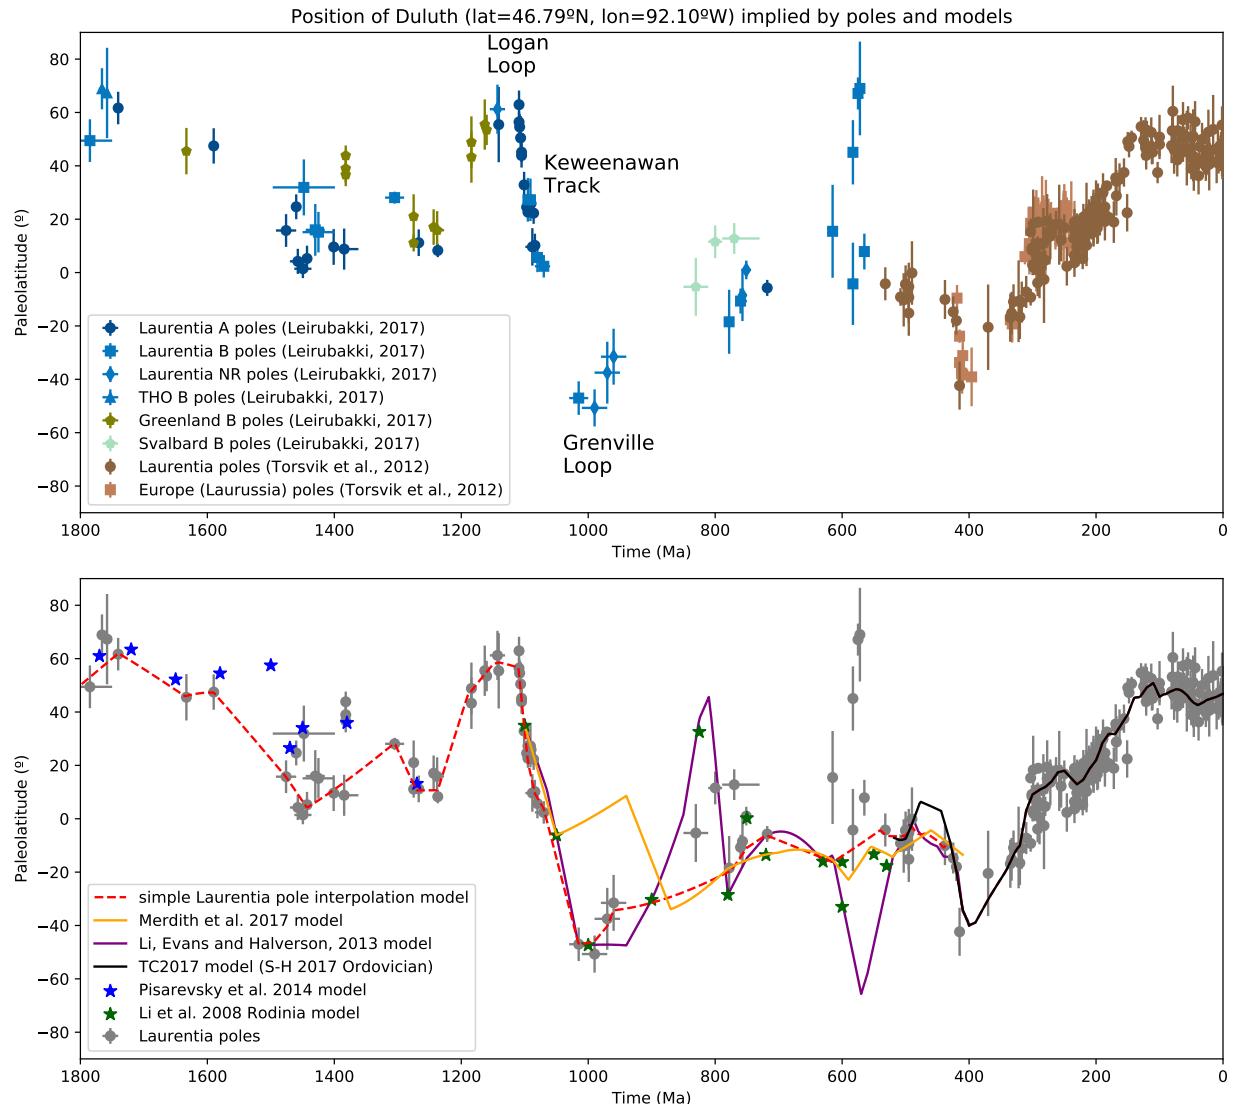

Figure 5. Top panel: Paleolatitude implied by paleomagnetic poles from Laurentia and associated blocks for Duluth (lat=46.79°N, lon=92.10°W). The paleomagnetic poles are compiled in Table 2. Bottom panel: Paleolatitude implied by Laurentia poles compared with that implied by published paleogeographic models and the simple Laurentia model used in this chapter for the reconstructions in Figure 6.

⁴²⁰ paleolatitude implied by this continuous model is shown in Figure 5. This path is based on
⁴²¹ Laurentia data alone which means that it is poorly constrained through intervals of sparse data
⁴²² (950-850 Ma for example). One could use interpretations of paleogeographic connections with
⁴²³ other cratons (e.g. Baltica in the early Neoproterozoic) to fill in such portions of the path,
⁴²⁴ however the result then becomes model-dependent without being constrained by data from
⁴²⁵ Laurentia itself. In portions of the record with a more dense record of poles, such as ca. 1450 Ma,
⁴²⁶ a calculated running mean is used to integrate constraints from multiple poles. This method
⁴²⁷ follows the approach taken in the Phanerozoic (e.g. Torsvik et al., 2012 wherein all poles within a
⁴²⁸ 20 Myr interval are averaged with the interval than progressively moved forward in 10 Myr steps.
⁴²⁹ When there are isolated ‘A’ grade poles without other temporally-similar poles, these poles are
⁴³⁰ fully satisfied in model. Where there are no constraints a simple interpolation between constraints
⁴³¹ is made. While data from Scotland and Svalbard are associated with Laurentia, the Scotland
⁴³² poles are poorly constrained in time and the Svalbard rotation to Laurentia is uncertain. These
⁴³³ poles are not utilized in the simple Laurentia model which means that the model as shown does
⁴³⁴ not include oscillatory true polar wander interpreted to have occurred ca. 810 and 790 Ma based
⁴³⁵ on data from Svalbard (Maloof et al., 2006). The model of Li et al. (2013) shown in Figure 5 does
⁴³⁶ seek to incorporate this true polar wander while also incorporating an interpretation of the
⁴³⁷ paleomagnetic pole record from South China.

⁴³⁸ One downside of a running mean approach is that it pulls the mean to regions of high data
⁴³⁹ density. As was shown in Swanson-Hysell et al. (2019), this behavior can reduce motion along an
⁴⁴⁰ apparent polar wander path. As a result, for the portion of the reconstruction during the interval
⁴⁴¹ of time ca. 1110 to 1070 Ma where there is high data density from the Midcontinent Rift, I utilize
⁴⁴² an Euler pole inversion from Swanson-Hysell et al. (2019).

⁴⁴³ Paleogeographic snapshots for the past position of Laurentia reconstructed using this synthesis
⁴⁴⁴ of the paleomagnetic poles are shown in Figure 6. These reconstructions use the tectonic elements
⁴⁴⁵ as defined by Whitmeyer and Karlstrom (2007) with these elements being progressively added
⁴⁴⁶ associated with Laurentia’s accretionary growth. As a reminder to the reader, paleomagnetic
⁴⁴⁷ poles provide constraints on the paleolatitude of a continental block as well as its orientation
⁴⁴⁸ (which way was north relative to the block). While they provide constraints in this regard, they

449 do not provide constraints in and of themselves for the longitudinal position of the block. Other
450 approaches to obtain paleolongitude utilize geophysical hypotheses such as assuming that large
451 low shear velocity provinces have been stable plume-generating zones in the lower mantle to
452 which plumes can be reconstructed (Torsvik et al., 2014) or that significant pole motion in certain
453 time intervals is associated with true polar wander axes with specified paleolongitudes that switch
454 through time in conjunction with the supercontinent cycle (Mitchell et al., 2012). In Figure 6,
455 Laurentia is centered on the longitudinal position of Duluth with the orientation and
456 paleolatitude being constrained by the paleomagnetic pole compilation as synthesized in the
457 simple Laurentia pole interpolation model (Fig. 5).

458 4.6 Comparing paleogeographic models to the paleomagnetic compilation

459 Developing comprehensive global continuous paleogeographic models is a major challenge given
460 the need to integrate and satisfy diverse geological and paleomagnetic data types. Continually
461 improving constraints related to tectonic setting from improved geologic and geochronologic data
462 need to be carefully integrated with the database of paleomagnetic poles. Paleomagnetic pole
463 compilations themselves are evolving with better data and improved geochronology. Efforts such
464 as this volume are therefore essential to present the state-of-the-art in terms of existing
465 constraints that can be used to evaluate current models and set the stage for future progress in
466 Precambrian paleogeography.

467 There is an overall lack of models in the literature for the Proterozoic with published
468 continuous rotation parameters that can be compared to the compilation of paleomagnetic poles
469 presented herein. The approach in the community for many years has been to publish models as
470 snapshots at given time intervals presented in figures without publishing continuous rotation
471 parameters, although some studies have published the Euler rotations associated with specified
472 times. With the further adoption of software tools such as GPlates, there has been significant
473 progress in the publication of continuous paleogeographic models constrained by paleomagnetic
474 poles through the Phanerozoic (540 Ma to present; e.g. Torsvik et al., 2012).

475 An exception to the paucity of published continuous paleogeographic models for the

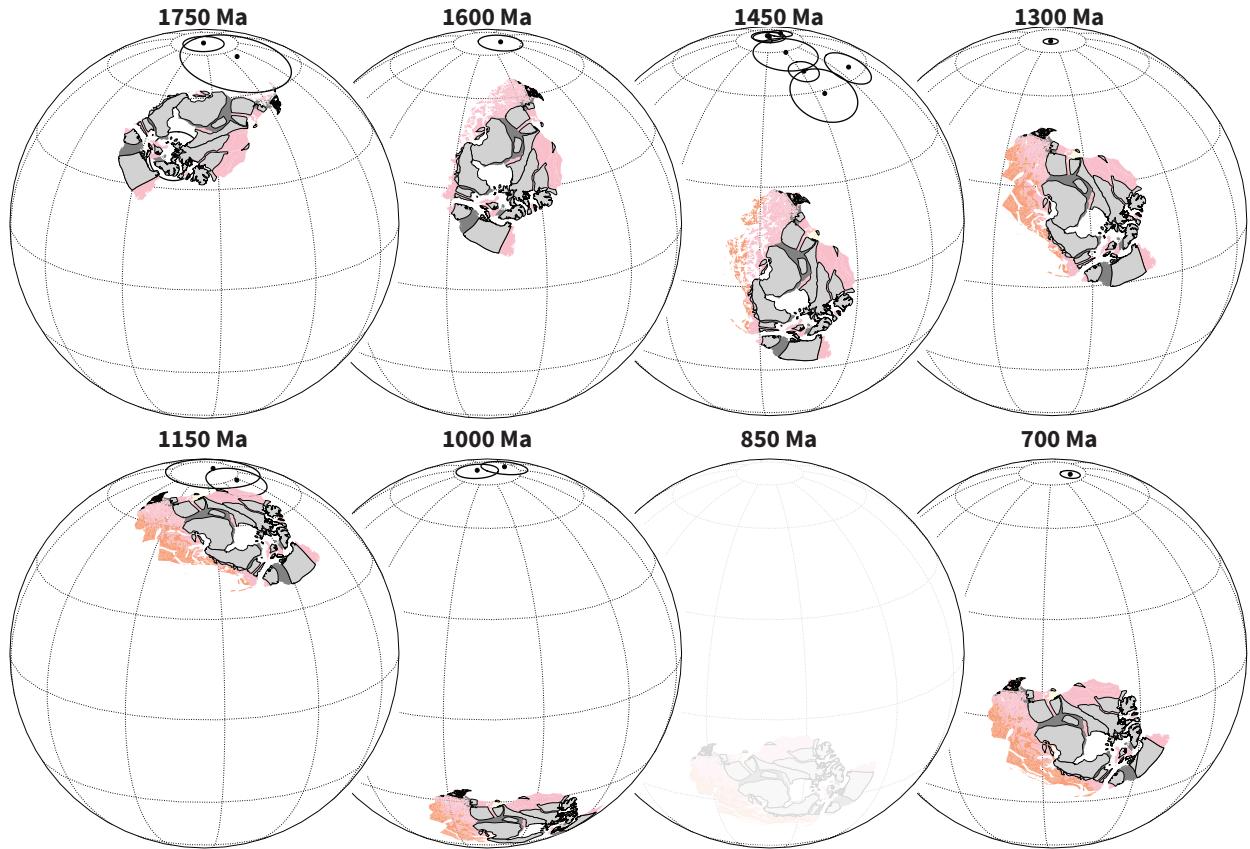

Figure 6. Paleogeographic reconstructions of Laurentia at time intervals through the Proterozoic that are well-constrained by paleomagnetic data. These reconstructions use the simple Laurentia pole interpolation model that is shown in Figure 5 and use this model to reconstruct the tectonic elements of Whitmeyer and Karlstrom (2007) shown in Figure 1. Modern coastlines are maintained in these polygons so that the rotated orientations can be interpreted by the reader in comparison to Figure 1. Paleomagnetic poles within 25 million years of each reconstruction time are plotted. All reconstructions have poles within such a time frame that provide constraints with the exception of the 850 Ma reconstruction which is shown faintly given this relative uncertainty in Laurentia's position.

⁴⁷⁶ Precambrian is the Neoproterozoic model of Merdith et al. (2017) which is shown in comparison
⁴⁷⁷ to the constraints for Laurentia in Figure 5. The extent to which the implied position of
⁴⁷⁸ Laurentia in Merdith et al. (2017) is consistent with the compiled paleomagnetic constraints can
⁴⁷⁹ be visualized in Figure 5. As noted above, the development of such models is challenging and the
⁴⁸⁰ researchers need to balance varying constraints. The focus here will be on the extent to which
⁴⁸¹ this model satisfies the available paleomagnetic poles for Laurentia. The model does not honor
⁴⁸² the Grenville loop (e.g. Laurentia going to moderately high southerly latitudes ca. 1000 Ma),
⁴⁸³ which is a striking departure from the paleomagnetic record and standard paleogeographic
⁴⁸⁴ models. Additionally, the implemented plate motion strays from the younger poles of the
⁴⁸⁵ Keweenawan Track and does not honor the Franklin LIP pole Denyszyn et al. (2009b) despite its
⁴⁸⁶ ‘A’ Nordic rating. The Franklin pole is taken to be a key constraint at the Tonian/Cryogenian
⁴⁸⁷ boundary that provides evidence both for the supercontinent Rodinia being equatorial and for ice
⁴⁸⁸ sheets associated with the Sturtian glaciation having extended to equatorial latitudes (Macdonald
⁴⁸⁹ et al., 2010).

⁴⁹⁰ There are more published models that show snapshots and publish rotation parameters
⁴⁹¹ associated with given time intervals such as the Rodinia model of Li et al. (2008) and the
⁴⁹² Mesoproterozoic model of Pisarevsky et al. (2014), without providing parameters for a continuous
⁴⁹³ model. The position for Laurentia implied by the Euler poles given for the model snapshots of
⁴⁹⁴ these studies are shown in Figure 5 and can be compared to the compiled record. The figure also
⁴⁹⁵ shows the continuous implied position of Laurentia from the late Mesoproterozoic into the early
⁴⁹⁶ Paleozoic from the model of (Li et al., 2013; while the model parameters were not published with
⁴⁹⁷ that study they have now been made available by the authors).

⁴⁹⁸ 4.7 Evaluating Laurentia’s Proterozoic paleogeographic neighbors

⁴⁹⁹ Note that this section is currently under development and is incomplete

500 **4.7.1 Amazonia**

501 In the central and southern Appalachians there are inliers of rocks that were metamorphosed
502 during the Ottawan phase of the Grenvillian orogeny (McLelland et al., 2013). On the basis of
503 whole-rock Pb-isotope data, Loewy et al. (2003) and Fisher et al. (2010) proposed that these
504 inliers are fragments of Amazonia lithosphere that were transferred to Laurentia during the
505 orogeny and left behind when the Iapetus Ocean formed. In particular, Fisher et al. (2010)
506 suggest the Sunsás orogen of Amazonia as the best match for southern and central Appalachian
507 inliers. This positioning leads to a paleogeographic model wherein Amazonia is a major portion of
508 the conjugate continental lithosphere that collided with Laurentia during Rodinia assembly
509 (Evans et al., 2013; Cawood and Pisarevsky, 2017). In this model, the basement inliers of the
510 Appalachian Orogen in the Blue Ridge region are interpreted to be the leading edge of Amazonia
511 with initial collision ca. 1080 initiating the Ottawan phase of the Grenvillian orogeny (Fig. 2).
512 Subsequent separation of Amazonia would have lead to the formation of the Iapetus Ocean as
513 Rodinia rifted apart. Departure of Amazonia potentially occurred as early as ca. 700 Ma in the
514 Paleo-Iapetus Ocean model of Robert et al. (2020).

515 **4.7.2 North China**

516 The latest Mesoproterozoic to earliest Neoproterozoic pole path of the North China craton
517 includes a swath of paleomagnetic poles with a similar arc length to the Keweenawan Track to
518 Grenville Loop of Laurentia's APWP (Zhao et al., 2019; Zhang et al., this volume). While the
519 chronostratigraphic age constraints on these North China poles are much looser than those from
520 Laurentia, Zhao et al. (2019) propose that the North China poles can be aligned with the
521 Keweenawan Track to reconstruct North China as being conjoined to the northwest margin of
522 Laurentia from prior to ca. 1110 Ma into the early Neoproterozoic. North China would have been
523 at polar latitudes ca. 1110 Ma and moved rapidly with Laurentia as it transited towards the
524 equator. Zhao et al. (2019) also argued that similarity in the detrital zircon age spectra between
525 early Neoproterozoic sediments in NW Laurentia and North China basins supports this
526 reconstruction. In particular, sediment transport from Laurentia could provide a source for ca.

527 1.18 Ga zircons (from the Shawinigan orogen) and ca. 1.08 Ga zircons (from the Grenville
528 orogen). In the Laurentia basins, ca. 1.6 Ga zircons without a clear Laurentia source could be
529 sourced from North China craton granites (e.g. Wang et al., 2020). If North China was in this
530 position, the timing of its arrival adjacent to Laurentia is unclear. The ca. 1220 Ma dikes pole of
531 the North China craton is not coincident with the ca. 1237 Ma Sudbury dikes pole in this
532 reconstructed position leading Zhao et al. (2019) and Zhang et al. (this volume) to suggest that
533 North China arrived on the Laurentian margin between ca. 1220 and 1110 Ma although they note
534 a lack of evidence for known North China orogenesis at this time. In terms of departing from this
535 position, one possibility is that its departure is associated with early Neoproterozoic extension in
536 northwest Laurentia.

537 **4.8 The record implies plate tectonics throughout the Proterozoic**

538 There is strong evidence both in Laurentia's geological and paleomagnetic record for differential
539 plate tectonic motion between 2.2 and 1.8 Ga. The continued history of accretionary orogenesis
540 and the evaluation of Laurentia's pole path in comparison to other continents from 1.8 Ga onward
541 supports the continual operation of plate tectonics throughout the rest of the Proterozoic and
542 Phanerozoic as well. While this evidence fits with the majority of interpretations of the timing of
543 initiation of modern-style plate tectonics (see summary in Korenaga, 2013), there continue to be
544 arguments proposing that a stagnant lid persisted through the Mesoproterozoic Era (1.6 to 1.0
545 Ga) and into the Neoproterozoic with plate tectonics not initiating until ca. 0.8 Ga (Hamilton,
546 2011; Stern and Miller, 2018). These arguments rest largely on the relative lack of Proterozoic
547 low-temperature high-pressure metamorphic rocks such as blueschists that form in subduction
548 zones (Stern et al., 2013). An alternative interpretation for this lack of blueschists in the
549 Proterozoic is that such a shift in metamorphic regime is the predicted result of secular evolution
550 of mantle chemistry rather than a harbinger of the onset of plate tectonics (Palin and White,
551 2015). While this line of evidence is intriguing, to argue that there was not differential plate
552 tectonic motion in the Paleoproterozoic and Mesoproterozoic is to ignore a vast breadth and depth
553 of geological and paleomagnetic data. From a paleomagnetic perspective, there is strong support
554 for independent and differential motion of the Slave and Superior provinces as is illustrated in

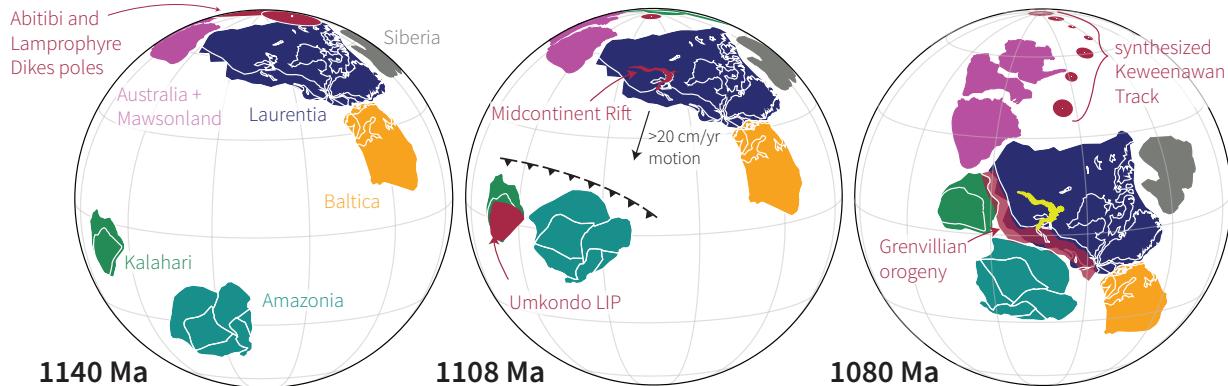

Figure 7. Paleogeographic reconstructions of Laurentia and other select Proterozoic continents leading up to Rodinia assembly in the late Mesoproterozoic modified from Swanson-Hysell et al. (2019). The record of paleomagnetic poles implies rapid motion which is consistent with the timing of collisional orogenesis associated with the Grenvillian orogeny.

555 Figure 4. From a geological perspective, the Trans-Hudson orogenic cycle, the Grenville orogenic
 556 cycle, and the Appalachian orogenic cycle are all well-explained with a mobilistic interpretation
 557 that includes phases of accretionary followed by collisional orogenesis (Fig. 2). One could counter
 558 that this perspective results from a plate-tectonic-centric viewpoint that lacks creativity to see
 559 the record as resulting from other processes than modern-style plate tectonics. However, in
 560 addition to the broad geological record showing an amalgamation of terranes as would be
 561 expected to arise through plate tectonics, there are also an obducted ophiolite as well as eclogites
 562 preserved in the Trans-Hudson orogen (Weller and St-Onge, 2017). These eclogites preserve
 563 evidence for high-pressure/low-temperature metamorphic conditions ca. 1.8 Ga. Similar to the
 564 Himalayan orogen, these rocks are interpreted to be the result of deep continental subduction and
 565 exhumation associated with convergent plate tectonics (Weller and St-Onge, 2017). Outside of
 566 Laurentia, there are examples of eclogites with geochemical affinity to oceanic crust such as that
 567 documented in the ca. 1.9 Ga Ubendian Belt of the Congo craton (Boniface et al., 2012).

568 Another perspective on Proterozoic tectonics, is that the record is one of intermittent
 569 subduction (Silver and Behn, 2008; O'Neill et al., 2013). In such a model, there are extended
 570 intervals with a stagnant lid alternating with intervals of differential plate motion. In particular,
 571 it has been argued that the Mesoproterozoic Era (1.6 to 1.0 Ga) is an interval when Earth was in
 572 a stagnant regime (Silver and Behn, 2008; O'Neill et al., 2013). The long-lived accretionary
 573 history of Laurentia following the amalgamation of the Archean provinces is difficult to reconcile

574 with such an interpretation (Figs. 1 and 2).

575 An additional constraint supporting ongoing plate tectonics throughout the Proterozoic comes
576 from the paleomagnetic record — in particular the paleomagnetic poles supported with baked
577 contact tests (Fig. ??). In a stagnant lid regime, there would not be sufficient heat flow across
578 the core-mantle boundary to sustain a geodynamo (Nimmo and Stevenson, 2000; Buffett, 2000).
579 Baked contact tests indicate that, at the time of dike emplacement, there was an appreciable field
580 such that both the cooling magma and the heated country rock in the vicinity of a dike were able
581 to acquire a primary coherent magnetization direction. Additionally, since paleomagnetic poles
582 are developed from many individual cooling units across a region, the similarity of the directions
583 across an igneous province indicates that the magnetizations were dominantly acquired from the
584 geomagnetic field rather than being influenced by local variable crustal magnetizations.
585 Therefore, the record supports the persistence of a geomagnetic field through the Paleoproterozoic
586 and Mesoproterozoic (Table 2) which implies active plate tectonics that enabled sufficient
587 core-mantle boundary heat flow to power the geodynamo. This interpretation of a significant
588 persistent geomagnetic field through much of the Proterozoic (with the potential exception of the
589 Ediacaran; Bono et al., 2019) is further bolstered by estimates of paleointensity obtained from
590 mafic dikes from Laurentia (e.g. Macouin et al., 2006) and elsewhere.

591 The record of these poles also show that there was progressive motion of Laurentia through the
592 Proterozoic (Figs. 5 and 6). Using data from Laurentia alone, however, it is difficult to ascertain
593 whether this motion is due to plate tectonic motion or rotation of the entire solid Earth through
594 true polar wander. True polar wander can lead to changing position relative to the spin axis even
595 with a stagnant lid. One interval when the Laurentian paleomagnetic record demands that some
596 of the motion is through differential plate tectonics is in the latest Mesoproterozoic. At that time,
597 the pole path is very well-resolved with many high-quality paleomagnetic poles between 1110 and
598 1070 Ma (Table 2; 3). The progression of the poles requires rotation about an Euler pole that is
599 distinct from a great circle path which would result if the motion were solely due to true polar
600 wander (Swanson-Hysell et al., 2019). These poles constrain rapid motion of Laurentia leading up
601 to collisional orogenesis associated with the Grenvillian orogeny, as illustrated in Figure 7. These
602 data provide strong evidence for differential plate motion at the time and are inconsistent with a

603 stagnant lid. Rather, the orogenic cycle of the Mesoproterozoic bears similarity with that of the
604 Paleozoic and reveals Laurentia to have been a central player in the building of amalgamated
605 continents associated with Rodinia and Pangea.

606 4.9 Conclusion

607 The paleogeographic record of Laurentia is rich in constraints through the Precambrian both in
608 terms of the geological and geochronological constraints on tectonism and the record of
609 paleomagnetic poles. Data from the Slave and Superior provinces of Laurentia provide what is
610 arguably the strongest evidence of differential plate tectonics in the Rhyacian and Orosirian
611 Periods of the Paleoproterozoic Era (2.3 to 1.8 Ga) leading up to the collision of these terranes
612 during the Trans-Hudson orogeny. The collisions of these and other Archean provinces led to the
613 formation of the core of Laurentia. Subsequent crustal growth occurred through multiple intervals
614 of accretionary orogenesis through the late Paleoproterozoic and Mesoproterozoic until the
615 continent-continent collision of the Grenvillian orogeny that was ongoing at the
616 Mesoproterozoic-Neoproterozoic boundary (1.0 Ga). The lead-up to this orogeny was associated
617 with rapid plate motion of Laurentia from high latitudes towards the equator recorded by the
618 Logan Loop and Keweenawan Track of paleomagnetic poles. Following, a return to high latitudes
619 as constrained by paleomagnetic poles of the Grenville Loop, Laurentia straddled the equator at
620 the time of Cryogenian Snowball Earth glaciation as part of the Rodinia supercontinent. Rifting
621 and passive margin development then isolated Laurentia in the early Paleozoic Era. Subsequent
622 accretionary and collisional orogenesis occurred associated with the Appalachian orogenic cycle
623 with Laurentia first colliding with Avalonia-Baltica to become Laurussia and Laurussia then
624 uniting with Gondwana to form Pangea. While the details of the conjugate continents are better
625 reconstructed for this last Wilson cycle, the broad features of the Trans-Hudson, Grenvillian and
626 Appalachian orogenic cycles bear similarities. In each case, accretionary collision of arc terranes
627 was followed by continent-continent collision. The major difference is that the collisions of the
628 Grenvillian and Appalachian orogenic cycles resulted in relatively minor crustal growth compared
629 to the Trans-Hudson. Break-up following the Grenvillian and Appalachian orogenic cycles
630 occurred along the same margin as collision while the major orogens of the Trans-Hudson orogenic

cycle have remained sutured. As a result, Laurentia has been a formidable continent for the past 1.8 billion years. As can be seen in the Chapters on Archean paleogeography (Salminen et al., this volume), Nuna (Elming et al., this volume) and Rodinia (Evans et al., this volume), the constraints from Laurentia are at the center of paleogeographic models through the Precambrian and will continue to be as the next generation of paleogeographic models are developed.

636 Acknowledgements

Many participants in the Nordic Paleomagnetism Workshop have contributed to the compilation and evaluation of the pole list utilized herein. Particular acknowledgement goes to David Evans for maintaining and distributing the compiled pole lists as well as additional efforts of Lauri Pesonen in maintaining the Paleomagia database (Veikkolainen et al., 2014). GPlates, and in particular the pyGPlates API, was utilized in this work (Müller et al., 2018). Figures were made using Matplotlib (Hunter, 2007) in conjunction with cartopy (Met Office, 2010 - 2015) and pmagpy (Tauxe et al., 2016) within an interactive Python environment (Pérez and Granger, 2007). The manuscript benefited from reviews from Athena Eyster, David Evans, and Lauri Pesonen as well as discussions with Francis Macdonald. This work was supported by NSF CAREER Grant EAR-1847277 awarded to N.L.S.-H. The chapter text as well as code, data, and reconstructions used in this paper are openly available and licensed for any form of reuse (CC BY 4.0) with attribution in this repository:

Table 1. Rotations of separated terranes

Block	Euler pole longitude	Euler pole latitude	rotation angle	note and citation
Greenland	-118.5	67.5	-13.8	Cenozoic separation of Greenland from Laurentia associated with opening of Baffin Bay and the Labrador Sea (Roest and Srivastava, 1989)
Scotland	161.9	78.6	-31.0	Reconstructing Atlantic opening following Torsvik and Cocks (2017)
Svalbard	125.0	-81.0	68	Rotate Svalbard to Laurentia in fit that works well with East Greenland basin according to Maloof et al. (2006)

Table 2: Compilation of paleomagnetic poles from Laurentia

terrane	unit name	Nordic rating	site lon (°)	site lat (°)	plon (°)	plat (°)	A ₉₅ (°)	age (Ma)	pole reference
Laurentia-Wyoming	Stillwater Complex - C2	A	249.2	45.2	335.8	-83.6	4.0	2705 ⁺⁴ ₋₄	Selkin et al. (2008)
Laurentia-Superior(East)	Otto Stock dykes and aureole	B	279.9	48.0	227.0	69.0	4.8	2676 ⁺⁵ ₋₅	Pullaiah and Irving (1975)
Laurentia-Slave	Defeat Suite	B	245.5	62.5	64.0	-1.0	15.0	2625 ⁺⁵ ₋₅	Mitchell et al. (2014)
Laurentia-Superior(East)	Ptarmigan-Mistassini dykes	B	287.0	54.0	213.0	-45.3	13.8	2505 ⁺² ₋₂	Evans and Halls (2010)
Laurentia-Superior(East)	Matachewan dykes R	A	278.0	48.0	238.3	-44.1	1.6	2466 ⁺²³ ₋₂₃	Evans and Halls (2010)
Laurentia-Superior(East)	Matachewan dykes N	A	278.0	48.0	239.5	-52.3	2.4	2446 ⁺³ ₋₃	Evans and Halls (2010)
