## The Precambrian paleogeography of Laurentia

Nicholas L. Swanson-Hysell<sup>1</sup>

<sup>1</sup> Department of Earth and Planetary Science, University of California, Berkeley, CA 94720 USA

This chapter is in preparation for the book Ancient Supercontinents and the Paleogeography of the Earth

### Introduction

- 2 Laurentia was a major continent throughout the majority of the Proterozoic and is hypothesized
- to have had a central position in both the Paleoproterozoic Nuna and Neoproterozoic Rodinia
- 4 supercontinents. The paleogeographic position of Laurentia is key to the development of
- 5 reconstructions of Proterozoic paleogeography. There is a rich record of Precambrian
- 6 paleomagnetic poles from Laurentia as well as an extensive geologic history of tectonism that are
- both key to evaluating and developing paleogeographic models. This chapter seeks to provide a
- 8 concise review of these records.

# 9 Broad tectonic history overview

- Laurentia refers to the craton that forms the Precambrian core of North America (Fig. 1).
- 11 Laurentia is comprised of multiple Archean provinces that had unique histories prior to their
- <sub>12</sub> amalgamation in the Paleoproterozoic, as well as tectonic zones of crustal growth that post-date
- this assembly (Hoffman, 1989; Whitmeyer and Karlstrom, 2007). Collision between the Superior
- province and the composite Slave+Rae+Hearne+Nain provinces that resulted in the
- 15 Trans-Hudson orogeny represents a major event in the formation of Laurentia (Corrigan et al.,
- 16 2009). Terminal collision recorded in the Trans-Hudson orogen is estimated to have been ca. 1.86
- to 1.82 Ga based on constraints such as U-Pb dating of monazite grains and zircon rims (??, e.g.).
- A period of accretionary and collision orogenesis is recorded in the constituent provinces and
- terranes of Laurentia leading up to the terminal collision of the Trans-Hudson orogeny. This

```
overall story of rapid Paleoproterozoic amalgamation of Laurentia's constituent Archean
   provinces, including the terminal Trans-Hudson orogeny, was synthesized in the seminal United
   Plates of America paper of Hoffman (1988) and has been refined in the time since – particularly
   with additional geochronological constraints. Of most relevance here are the events that led to the
   suturing of more major Archean provinces: the Thelon orogen associated with the collision
   between the Slave province and the Rae province ca. 2.0 to 1.9 Ga (Hoffman, 1989); the Snowbird
   orogen associated with ca. 1.89 Ga collision between the Rae and Hearne provinces and
   associated terranes (Berman et al., 2007); the Nagssugtoqidian orogen due to the ca. 1.86 to 1.84
27
   Ga collision between the Rae and Nain provinces (?); and the Torngat orogen resulting from the
   ca. 1.87 to 1.85 Ga collision of the Meta Incognita province (grouped with the Rae province in
   older compilations) with the Nain province (?). As for the Wyoming province, many models posit
   that it was conjoined with Hearne and associated provinces at the time of the Trans-Hudson
   orogeny (e.g. ?Pehrsson et al., 2015) or was proximal to Hearne and Superior while still
   undergoing continued translation up to ca. 1.80 Ga (Whitmeyer and Karlstrom, 2007). A
   contrasting view has been been proposed that the Wyoming province and Medicine Hat blocks
   was not conjoined with the other Laurentia provinces until ca. 1.72 Ga (Kilian et al., 2016). This
35
   interpretation is argued to be consistent with geochronological constraints on monazite and
   metamorphic zircon indicating active collisional orogenesis associated with the Big Sky orogen on
   the northern margin of the craton as late as ca. 1.75 to 1.72 Ga (Condit et al., 2015) and ca. 1.72
   tectonomagmatic activity in the Black Hills region (Redden et al., 1990). However, the evidence
   for earlier orogenesis ca. 1.78 to 1.75 in the Black Hills (Dahl et al., 1999; Hrncir et al., 2017), as
   well as high-grade tectonism as early as ca. 1.81 Ga in the Big Sky orogen (Condit et al., 2015),
   may support the interpretation of Hrncir et al. (2017) that ca. 1.72 Ga activity is a minor
   overprint on ca. 1.75 terminal suturing between Wyoming and Superior. Regardless, in both of
   these interpretations, Wyoming is a later addition to Laurentia with final suturing post-dating ca.
   1.82 Ga amalgamation of Archean provinces with the Trans-Hudson orogen further to the
   northeast. Overall, the collision of these Archean microcontinents between ca. 1.9 and 1.8 Ga
   lead to rapid amalgamation of the majority of the Laurentia craton.
```

48 Crustal growth also progressed at this time in the Paleoproterozoic through accretionary

Figure 1. Simplified map of Laurentia showing the location of Archean provinces (labeled with text) and younger Paleoproterozoic and Mesoproterozoic crust (simplified from Whitmeyer and Karlstrom, 2007). The localities from which the compiled Precambrian paleomagnetic poles were developed are shown and colored by age. The circles (A rated poles) and squares (B rated poles) have been assessed by the Nordic workshop panel while the diamonds are additional not-rated results from the Paleomagia database.

```
orogenesis. This accretion occurred within the Wopmay orogen through ca. 1.88 Ga arc-continent
   collision that led to the accretion of the Hottah terrane (the Calderian orogeny) and the
   subsequent emplacement of the Great Bear magmatic zone from ca. 1.88 to 1.84 Ga (Hildebrand
   et al., 2009). Coeval with the Trans-Hudson or or was the perphiral Penokean or or the
   southern margin of the Superior province with the last evidence of that orogeny being ca. 1.78
   undeformed plutons of the East Central Minnesota Batholith (Holm et al., 2005).
      In the paleogeographic model framework of Pehrsson et al. (2015), the collisions of provinces
55
   and terranes leading up to the Trans-Hudson orogeny mark the initial phase of assembly of the
   supercontinent Nuna. The Trans-Hudson orogeny itself is taken to be the terminal collision
   associated with the closure of the Manikewan Ocean that had previous been a large oceanic tract
   separating the Superior province from the composite Slave+Rae+Hearne+Nain provinces (often
   referred to as the Churchill domain or plate; e.g. ??). The Pehrsson et al. (2015) model posits
   that this period terminal collision not only resulted in the amalgamation of Laurentia, but is also
   associated with the assembly of the supercontinent Nuna that is hypothesized to include other
   major Paleoproterozoic cratons including Siberia, Congo/São Francisco, West Africa, and
   Amazonia (Whitmeyer and Karlstrom, 2007; Pehrsson et al., 2015).
      Following the Trans-Hudson orogeny, the locus of orogenesis migrated to the exterior of
   Laurentia. This change marks a shift in the predominant style of Laurentia's growth as subsequent
   crustal growth occurred dominantly through accretion of juvenile crust along the southern and
   eastern margin of the nucleus of Archean provinces (Whitmeyer and Karlstrom, 2007; Figs. 1 and
   2). Determining the extent of these belts is complicated by poor exposure of them in the
   midcontinent relative to the exposure of the Archean provinces throughout the Canadian shield.
   Major growth of Laurentia following the amalgamation of these Archean provinces occurred
   associated with the arc-continent collision of the ca. 1.71 to 1.68 Ga Yavapai orogeny. Yavapai
   orogenesis is interpreted to have resulted from the accretion of a series of arc terranes that
   collided with each other and Laurentia (Whitmeyer and Karlstrom, 2007). Yavapai accretion was
   followed by widespread emplacement of granitoid intrusions (Whitmeyer and Karlstrom, 2007).
   These intrusions are hypothesized to have stabilized the juvenile accreted terranes that
   subsequently remained part of Laurentia (Whitmeyer and Karlstrom, 2007). Subsequent
```

```
accretionary orogenesis of the ca. 1.65–1.60 Ga Mazatzal Orogeny and associated plutonism lead
    to further crustal growth in the latest Paleoproterozoic (Whitmeyer and Karlstrom, 2007).
   Laurentia's growth continued in the Mesoproterozoic along the southeast margin through further
   juvenile terrane and arc accretion. An interval of major plutonism occurred ca. 1.48–1.35 Ga
   leading to the formation of A-type granitoids throughout both Mesoproterozoic and
   Paleoproterozoic provinces extending from the southwest United States up to the Central Gneiss
    Belt of Ontario to the northeast of Georgian Bay (Slagstad et al., 2009). This plutonism is likely
    due to crustal melting within a back-arc region of ca. 1.50 to 1.43 Ga accretionary orogenesis
    (Bickford et al., 2015). Younger magmatic activity ca. 1.37 Ga of the Southern Granite-Rhyolite
    Province suggests a similar tectonic setting of accretionary orogenesis at that time (Bickford
    et al., 2015). While an active margin interpretation with magmatism in back-arc setting has
    gained traction within the literature with evidence, the tectonic setting is considered enigmatic
    given earlier interpretations of an anorogenic setting (see references in Slagstad et al., 2009).
       Accretionary orogenesis continued along the (south)east margin of Laurentia with the
91
   arc-continent collision of the ca. 1.25-1.22 Ga Elzevirian orogeny (McLelland et al., 2013). The
92
   subsequent ca. 1.19 to 1.16 Ga Shawinigan orogeny is interpreted to be due to the accretion of a
    terrane comprised of amalgamated arc volcanics and associated metasediments and is followed by
    a period of tectonic quiescence on the eastern margin of Laurentia until the collision orogenesis of
   the Grenvillian orogeny (McLelland et al., 2010). In the latest Mesoproterozoic (ca. 1.11-1.08
    Ga), a major intracontinental rift co-located with a large igneous province formed in Laurentia's
    interior leading to extension within the Archean Superior province and Paleoproterozoic
    provinces. This Midcontinent Rift lead to the formation of a thick succession of volcanics and
   mafic intrusions that are well-preserved in Laurentia's interior. Midcontinent Rift development
    ceased as major collisional orogenesis of the Grenvillian orogeny began (Swanson-Hysell et al.,
    2019). The Grenvillian orogeny was a protracted interval of continent-continent collision (ca. 1.09)
102
   to 0.98 Ga) leading to amphibolite to granulite facies metamorphism through the orogen
    (McLelland et al., 2010). The orogeny is interpreted to have resulted in the development of a
104
    thick orogenic plateau (Rivers, 2008).
```

There was significantly less crustal growth on the western margin of Laurentia (Fig. 1) and the

105

106

Figure 2. Simplified summary of Laurentia's tectonic history over the past  $\sim 1.8$  billion years. Brief summaries and references related to the orogenic and rifting episodes are given in the text. Note that the Penokean orogeny overlaps with the Trans-Hudson orogeny and is not shown.

Mesoproterozoic tectonic history is not as well elucidated as on the southern to eastern margin.

The 15 to 20 km thick package of sedimentary rocks of the Belt-Purcell Supergroup is associated with ca. 1.47 to 1.40 intracontinental rift – the tectonic setting of which is debated. Hoffman (1989) proposed that it may be a remanent back-arc basin trapped within a continent, while others envision it as being associated with continental rifting along the margin associated with separation of a conjugate continent (Jones et al., 2015, e.g.). This region is interpreted to have been subsequently deformed during a ca. 1.36 to 1.33 event known as the East Kootenay orogeny (McMechan and Price, 1982; Nesheim et al., 2012; McFarlane, 2015).

This late Paleoproterozoic and Mesoproterozoic tectonic history provides significant 115 constraints on paleogeographic reconstructions. In particular, the long-lived history of 116 accretionary orogenesis along the southeast (present-day coordinates) of Laurentia from the 117 initiation of the Yavapai orogeny (ca. 1.71 Ga) to the end of the Shawinigan orogeny (ca. 1.06 118 Ga) requires a long-lived open margin without a major conjugate continent up until the time of terminal Grenvillian orogeny collision (Karlstrom et al., 2001). This constraint is incorporated 120 into models such as that of Pehrsson et al. (2015) which maintain a long-lived convergent margin 121 throughout the Mesoproterozoic, but in some reconstructions other continental blocks are 122 reconstructured into positions that are seemingly incompatible with this record of accretionary 123 orogenesis (e.g. Amazonia in Elming et al., 2009). The high-grade metamorphism associated with 124 the Ottawan phase of the Grenvillian orogeny itself requires a collision between Laurentia and 125 (an)other continent(s) ca. 1080 Ma – the geological observation of which first lead to the 126 formulation of the hypothesis of the supercontinent Rodinia (Hoffman, 1991). That the Laurentia 127 margin experienced large-scale continent-continent collision at the time of the Ottawan Phase of 128 the Grenvillian orogeny that is recorded in Texas, up through the Blue Ridge Appalachian inliers, through Ontario and up to the Labrador Sea remains a strong piece of evidence that a 130 supercontinent or (proto)supercontinent formed at the 1.0 Ga Mesoproterozoic to Neoproterozoic 131 transition. 132

The subsequent Neoproterozoic tectonic history of Laurentia is dominantly a record of rifting.

Along the western margin of Laurentia, small-scale rifting occurred ca. 780 to 720 Ma leading to

deposition in basins that is recorded from the Death Valley region of SW Laurentia up to the

Mackenzie Mountains of NW Laurentia (Roonev et al., 2017). However, this extensional basin development is relatively minor and predates the more significant rifting that lead to passive margin thermal subsidence that did not occur until the Ediacaran (closer to the ca. 539 Ma 138 Neoproterozoic-Phanerozoic boundary: Bond et al., 1984; LEVY and CHRISTIE-BLICK, 1991). 139 The emplacement of the ca. 780 Ma Gunbarrel large igneous province along this margin and the subsequent extension recorded in the basins is commonly interpreted to be associated with the break-up of Laurentia and a conjugate continent to the western margin. If this interpretation is correct, it is unclear why there would be minimal thermal subsidence until the Ediacaran (post 143 635 Ma as in LEVY and CHRISTIE-BLICK, 1991 and Witkosky and Wernicke, 2018). The geological evidence therefore supports active tectonism along the western margin of Laurentia. 145 but suggests that more dramatic lithospheric thinning occurred later than the timing of rifting 146 typically implemented in models of Rodinia break-up. One possibility, along the lines of that proposed in Ross (1991), is that ca. 780 Ma extensional tectonism is an inboard record of rifting 148 and passive margin development that occurred further outboard. In this model, subsequent 149 continent rifting that drove lithospheric thinning, perhaps associated with the departure of a 150 microcontinent fragment rather than an already departed major conjugate continent, would be 151 the cause of Ediacaran to Cambrian thermal subsidence. The margin that did experience 152 large-scale rifting and associated passive margin thermal subsidence earlier in the Neoproterozoic 153 is the northeast Greenland margin. Available geochronological constraints and thermal subsidence modeling indicate ca. 820 Ma rifting followed by thermal subsidence of a stable 155 platform (Maloof et al., 2006; Halverson et al., 2018). These data suggest that conjugate 156 continental lithosphere rifted away from northeast Greenland ca. 820 Ma. 157

Extensive rifting that was followed by thermal subsidence occurred along the southeast to east
Laurentia margin leading up to the Neoproterozoic-Phanerozoic boundary and is interpreted to be
associated with the opening of the Iapetus ocean. A record of this rifting is preserved as rift
basins that were part of failed arms (Rome trough, Reelfoot rift and Oklahoma aulacogen) as well
as prolonged Cambrian to Ordovician passive margin thermal subsidence along the margin (Bond
et al., 1984; Whitmeyer and Karlstrom, 2007). The age of igneous intrusions that have been
interpreted to be rift-related play a significant role in interpretations of this history such as in the

rift development model of Burton and Southworth (2010). In this model, spatially-restricted rifting occurs ca. 760 to 680 Ma in the region of modern-day North Carolina and Virginia. Ca. 620-580 Ma rifting initiates in the region from modern-day New York to Newfoundland and by ca. 167 580 to 550 Ma rifting extends along the length of Laurentia's eastern margin. The last phases of 168 this rifting are associated with the separation of the Argentine pre-Cordillera Cuyania terrane 169 (Dickerson and Keller, 1998). Cuyania is widely interpreted be a rifted fragment of SE Laurentia 170 that separated associated with this early Cambrian rifting and subsequently became part of 171 Gondwana when it collided with other terranes in the vicinity of the Rio de Plata craton during 172 the Ordovician Famatinian orogeny (Martin et al., 2019). As with other rifts, it is difficult to distinguish the separation of a cratonic fragment as a microcontinent from the rifting of a major 174 craton as the record that lingers on the craton is similar. One interpretation is that there was 175 successful break-up along the eastern margin during the ca. 580 to 550 Ma interval of rifting prior 176 to the ca. 539 Oklahoma aulacogen rifting that liberated the Cuyania microcontinent. The 177 Maz-Areguipa-Rio Apa (MARA) block MARA block with which Cuyania collided (Martin et al... 178 2019) is likely a product of such rifting. Orogenesis between the MARA block and the Rio de 179 Plata and Kalahari in the ca. 530 Ma Pampean orogeny (Casquet et al., 2018) predated the 180 collision of Cuvania during the ca. 460 Famatinian orogeny. 181

The eastern margin of Laurentia then went through the cycle of Appalachian orogenesis. As is 182 visualized in Figure 2, there are parallels between the Grenville orogenic interval and the 183 Appalachian orogenic interval in that there was a period of arc-continent collision (Shawinigan 184 orogeny in the Grenville interval; Taconic orogeny in the Appalachian interval) followed by 185 microcontinent accretion (Llano in the Grenville interval; Acadian in the Appalachian interval) 186 that culminated in large-scale continent-continent collision (Grenvillian orogeny in the Grenville interval; Alleghanian in the Appalachian interval). These similarities are the consequence of an 188 active margin facing an ocean basin that was progressively consumed until its consumption 189 resulted in continent-continent collision. In the case of the Grenville interval, this terminal collision is interpreted to be associated with the assembly of the supercontinent Rodinia and in 191 the Appalachian interval it is interpreted to be associated to with the assembly of the 192 supercontinent Pangea.

Even without considering other continents on Earth, the geological record of Paleoproterozoic collisional of Archean provinces combined with accretionary orogenesis at that time and through the rest of the Paleoproterozoic and Mesoproterozoic provides very strong evidence for mobile plate tectonics driving Laurentia's evolution throughout the past 2 billion years. This tectonic history inferred from geological data can be enhanced through integration with the paleomagnetic record.

### 200 Paleomagnetic pole compilation

In this chapter, I focus on the compilation of paleomagnetic poles developed through the Nordic 201 Paleomagnetism Workshops with some additions and modifications. The Nordic Paleomagnetism 202 Workshops have taken the approach of using expert panels to assess paleomagnetic poles and 203 assign them grades meant to convey the confidence that the community has in these results. 204 While many factors associated with paleomagnetic poles can be assessed quantitatively through 205 Fisher statistics and the precision of geochronological constraints, other aspects such as the degree to which available field tests constrain the magnetization to be primary require expert 207 assessment. The categorizations used by the expert panel are 'A' and 'B' with the last panel 208 meeting occurring in Fall 2017 in Leirubakki, Iceland. An 'A' rating refers to poles that are 200 judged to be of such high-quality that they provide essential constraints that should be satisfied 210 in paleogeographic reconstructions. A 'B' rating is associated with poles that are judged to likely 211 provide a high-quality constraint, but have some deficiency such as remaining ambiguity in the 212 demonstration of primary remanence or the quality/precision of available geochronologic 213 constraints. Additional poles that were not given an 'A' or 'B' classification at the Nordic 214 Workshops are referred to as not-rated ('NR'). These additional poles are taken from the 215 Paleomagia database (?). Many of these poles are quite valuable for reconstruction and should 216 not be dismissed from being considered in paleogeography reconstructions. For example, there are rich data associated with intrusive lithologies of the Grenville Province that are the available 218 paleomagnetic constraints for Laurentia at the Mesoproterozoic-Neoproterozoic boundary. 219 However, the ages of the remanence associated with these poles is complicated by the reality that

the magnetization was acquired during exhumation and such cooling ages are more difficult to robustly constrain than for eruptive units or shallow-level intrusions. As a result, the vast majority of Grenville Province poles are not given an 'A' or 'B' rating. However, while any one of these Grenville poles could be interpreted to suffer from temporal uncertainty, the overall preponderence of poles in a similar location at the time suggests that they need to be taken seriously within any paleogeographic reconstruction of Laurentia (although note an alternative view of an allochthonous origin discussed below).

Prior to the termination of the Trans-Hudson orogeny (before 1.8 Ga), I consider 228 paleomagnetic poles with respect to the individual Archean provinces. There are poles in the 229 compilation for the Slave, Wyoming, Rae, Superior and Nain provinces prior to Laurentia 230 amalgamation. A lingering question raised in? that still lingers is whether the Archean provinces 231 each had independent drift histories with significant separation or whether they have shared 232 histories before experiencing fragmentation and remanalgamation. Overall, these data provide an opportunity to re-evaluate the paleomagnetic evidence for relative motions between Archean 234 provinces prior to Laurentia assembly. Following the termination of this orogeny (after 1.8 Ga), I 235 consider poles from all the respective provinces and terranes to reflect the position of all of 236 Laurentia. 237

For the Superior province, an additional complexity is that paleomagnetic poles from Siderian 238 to Rhyacian Period (2.50 to 2.05 Ga) dike swarms, as well as deflection of dike trends, support an 230 interpretation that there was substantial Paleoproterozoic rotation of the western Superior 240 province relative to the eastern Superior province across the Kapuskasing Structural Zone (Bates 241 and Halls, 1991; Evans and Halls, 2010). This interpretation is consistent with the hypothesis of 242 Hoffman (1988) that the Kapuskasing Structural Zone represents major intracratonic uplift 243 related to the Trans-Hudson orogeny. Evans and Halls (2010) propose an Euler rotation of (51°N, 85°W, -14°CCW) to reconstruct western Superior relative to eastern Superior and interpret that 245 the rotation occurred in the time interval of 2.07 to 1.87 Ga. I follow this interpretation and 246 group the poles into Superior (West) and Superior (East). These poles are shown in Table 1 both in their initial reference frame and rotated into the other Superior reference frame. Uncertainty 248 remains with respect to whether the ca. 1.88 Ga Molson dikes pole pre-dates or post-dates this

rotation and thus for the time-being should be considered solely in the western Superior province reference frame.

Following Laurentia's amalgamation, poles from each part of Laurentia can be considered to 252 reflect the position of the entire composite craton. It is worth considering the possibility that 253 poles from zones of Paleoproterozoic and Mesoproterozoic accretion could be allochthonous to the 254 craton. Halls et al. (2015) argued that this was the case for late Mesoproterozoic and early Neoproterozoic poles from east of the Grenvillian allochthon boundary fault. However, the 256 majority of researchers have considered these poles to post-date major differential motion and be 257 associated with cooling during collapse of a thick orogenic plateau developed during 258 continent-continent collision (e.g. Brown and McEnroe, 2012). Poles with a B-rating are also 259 included in the composite that come from Greenland, Svalbard and Scotland. These terranes were 260 once part of contiguous Laurentia, but have subsequently rifted away. These poles need to be 261 rotated into the Laurentia reference frame prior to use for tectonic reconstruction and I apply the following rotations: 263

|           | Euler pole | Euler pole | rotation | note and                         |
|-----------|------------|------------|----------|----------------------------------|

|           |            |            |          | Maloof et al. (2006)             |

Table 1

Through the Proterozoic there are intervals where there are abundant paleomagnetic poles
that constrain Laurentia's position and intervals when the record is quite sparse. The implied
paleolatitudes for an interior point on Laurentia is shown in Figure 4. There are many
high-quality paleomagnetic poles in the early Mesoproterozoic with 12 poles between ca. 1480 and
1380 from Laurentia (including Greenland poles). The best-constrained portion of the record is
associated with 1110 to 1083 Ma magnatism within the Midcontinent Rift and southwest

Figure 3. Top panel: Paleomagnetic poles from 1800 to 560 Ma for Laurentia (including Greenland, Scotland and Svalbard). Bottom panel: Paleomagnetic data for Archean Provinces prior to the amalgamation of Laurentia.

- Laurentia that enables the development of well-calibrated apparent polar wander path
  (Swanson-Hysell et al., 2019). The late Tonian Period also has a number of poles the Gunbarrel
  and Franklin large igneous provinces as well as contemporaneous sedimentary rocks.
- These paleomagnetic poles can be used to develop paleogeographic reconstructions for
  Laurentia alone. Paleogeographic snapshots for the past position of Laurentia are shown in Figure

  ??. These reconstructions use the tectonic elements as defined by Whitmeyer and Karlstrom

  (2007) with these elements being progressively added associated with Laurentia's growth.
- As a reminder to the reader, paleomagnetic poles provide constraints on the paleolatitude of a continental block as well as its orientation (which way was north relative to the block). While they provide constraints in this regard, they do not provide constraints in and of themselves of the longitudinal position of the block. Other approaches to obtain paleolongitude utilize geophysical hypotheses that are actualized through different methods such as assuming that large low shear velocity provinces have been stable plume-generating zones in the lower mantle to which plumes can be reconstructed.
- The synthesis of Pesonen et al. (2012) developed reconstructions at various Proterozoic time slices.
- To make an argument that differential plate tectonic motion began in the Neoproterozoic is to ignore a vast breadth and depth of geological and paleomagnetic data.
